Aging Eyes, Infant Eyes, and Excitable Tissues

The eyes and the lungs are sensitive tissues that are easily harmed by inappropriate environmental exposure. They are especially sensitive in infancy and old age.

For 60 years there have been controversies about the cause of retinopathy of prematurity, which has blinded tens of thousands of people.

Degeneration of the retina is the main cause of blindness in old people. Retinal injury is caused by ordinary light, when the eyes are sensitized by melatonin, prolactin, and polyunsaturated fats. Bright light isn't harmful to the retina, even when it is continuous, if the retina isn't sensitized.

Melatonin and prolactin are induced by stress, and darkness is a stress because it impairs mitochondrial energy production.

The polyunsaturated fats which accumulate in the brain and retina damage mitochondria.

Iron, which accumulates prenatally, and then again with aging, reacts with unsaturated fats during stress to destroy cells.

The popular supplements melatonin, tryptophan, fish oils, St. John's wort, and the various omega -3 oils, all increase the risk of retinal light damage and macular degeneration. Serotonin uptake inhibiting antidepressants are suspected to be able to cause it.

Processes similar to those that damage the over-sensitized retina can occur in other cells, as a result of stress. The substances that sensitize the retina to light-damage, can also increase the incidence of new or metastatic cancers.

Iron supplements and the use of supplemental oxygen, especially with a vitamin E deficiency exacerbated by excessive unsaturated fats in the diet, are still commonly used exactly when they can do the most damage.

One of the recognized achievements of biology has been the demonstration of life's universality, in the sense that organisms of all sorts use the same fundamental genetic code, and that yeasts, lizards, apes, and people have remarkably similar cellular systems, as well as a great amount of genetic similarity.

There has been another, less well recognized, sort of convergence going on in physiology and pathophysiology. Hans Selye's concept of stress, "the syndrome of being sick," Otto Warburg's argument that a "respiratory defect" was behind all kinds of cancer, and the idea of free radical damage as a common factor in disease and aging, helped to create a more general way of looking at the nature of disease that superceded medicine's theories of disease pathogens and genetic mutations, which created thousands of "disease entities," none of which had much to do with the individuality of the patient or his environment.

The understanding that plants and animals have much biochemistry in common has gradually changed the assumptions of the science establishment, which until recently insisted that only "ionizing radiation" could affect animals or other organisms that lacked chlorophyll--and insisted that ionizing rays acted only on the DNA. Visible light, the textbooks said, was not "chemically active," and so couldn't possibly affect animals' cells. In animals, coloration was seen mainly as decoration and disguise, rather than as a functional part of their biochemistry.

(Chemically, the meaning of "a pigment" is that it's a chemical which selectively absorbs radiation. **Old observations such as Warburg's, that visible light can restore the activity of the "respiratory pigments," showed without doubt that visible light is biochemically active.** By the 1960s, several studies had been published showing the inhibition of respiratory enzymes by

blue light, and their activation by red light. The problem to be explained is why the science culture simply couldn't accept crucial facts of that sort.)

The retina, of course, was allowed (in the views of mainline science) to respond to ordinary light, but the few people who studied the biological effects of seasonal or daily cycles of light have until recently stayed very close to the nerve pathways leading from the retina to the pineal gland, because those pathways could be described in terms of an evolutionarily specialized "third eye." Even with a doctrine of a genetically specialized link between the retina and a little of the animal's physiological chemistry, the great, slow-witted science establishment has done its best to avoid thoughts of any deep interaction between an organism and its environment, by insisting that the organism runs according to a genetically determined "clock" which is located in a few cells in a certain area of the brain, and that nervous impulses from the retina have only the small privilege of "setting the clock."

It didn't matter to the academic and medical worlds that a professor, Frank A. Brown, had long ago disproved the idea of an innate genetic "clock," because philosophy is much stronger than evidence. Leibniz had said that everything in the world runs on its own inner clock, without needing to perceive its surroundings, and this idea that everything in the world is a "windowless monad" resonated through the world of science, because it justified the pompous authoritarian attitudes of the experts who knew that anything that wasn't already in their heads couldn't be considered knowledge. **If an organism's "essence is contained in its genes," then it clearly doesn't interact in any meaningful way with most of its environment.** This is the sort of culture that imbued research on the biology of light cycles.

When I moved from Mexico, first to Montana and then to Oregon in 1966, I became very conscious of how light affects the hormones and the health. (For example, in Montana I experienced an interesting springtime shedding of body hair.) Many people who came to cloudy Eugene to study, and who often lived in cheap basement apartments, would develop chronic health problems within a few months. Women who had been healthy when they arrived would often develop premenstrual syndrome or arthritis or colitis during their first winter in Eugene.

The absence of bright light would create a progesterone deficiency, and would leave estrogen and prolactin unopposed. Beginning in 1966, I started calling the syndrome "winter sickness," but over the next few years, because of the prominence of the premenstrual syndrome and fertility problems in these seasonally exacerbated disorders, I began calling it the pathology of estrogen dominance. In the endocrinology classes I taught at the National College of Naturopathic Medicine, I emphasized the importance of light, and suggested that medicine could be reorganized around these estrogen-related processes. If the sparrows of Times Square mated in the winter because of the bright lights, it seemed clear that bright artificial light would be helpful in regulating human hormones.

In our lab at the University of Oregon, our hamsters would try to hibernate, even though they were in temperature-controlled laboratories with regular cycles of artificial light. (The ceiling lights provided only dim illumination inside their cage boxes, so they were probably in a chronic state of light deprivation, which probably increased their sensitivity to the weak environmental cues that Frank Brown had investigated, possibly microwaves that easily penetrated the lab walls.) During the winter, when they were infertile, I found that their thymus glands practically disappeared. The mechanism seemed to include the increase of pineal gland activity (probably increasing melatonin synthesis) in the winter, under the intensified activity of the "sympathetic nervous system" (with increased activity of adrenalin and other catecholamines), and the melatonin was apparently a signal for suppressing fertility during the stressful winter. In some animals (Shvareva and Nevretdinova, 1989), estrogen is increased during hibernation, contributing to the reduction of body temperature.

In 1994 A.V. Sirotkin found that melatonin inhibits progesterone production but stimulates estrogen production, and it's widely recognized that melatonin generally inhibits the thyroid hormones, creating an environment in which

fertilization, implantation, and development of the embryo are not possible. This combination of high estrogen with low progesterone and low thyroid decreases the resistance of the organism, predisposing it to seizures and excitotoxic damage, and causing the thymus gland to atrophy.

Cyclical exposure to melatonin can have an effect on the reproductive system opposite to that of chronic exposure, and the way exogenous melatonin is delivered to the animal can have unexpected effects on the actual amount of melatonin circulating in the blood (Wright and Alves, 2001). The actual amount of melatonin in the tissues, its relation to the normal cycling of the animal, and the influence of temperature, are often disregarded in melatonin research, making it hard to interpret many of the publications.

There is a lot of talk about melatonin's function as an antioxidant, but, like so many other "antioxidants," melatonin can act as a pro-oxidant at physiologically relevant concentrations; some studies have found that it, like estrogen, increases the activity of the pro-oxidative free radical nitric oxide (which acts like melatonin on pigment cells, causing them to lighten). The promoters of estrogen are also making claims that estrogen is a protective antioxidant, though that isn't true of physiological concentrations of the estrogens, which can catalyze intense oxidations. The market culture seems to guide most research in these substances.

Almost any kind of stress increases the formation of melatonin.

In some animals, melatonin has been shown to be responsible for whitening of the hair during the winter. In some species it acts directly on the pigment cells, but in other species it seems to inhibit the action of the melanocyte stimulating hormone.

In snowy climates, it's "ecologically" rational for animals to turn white in the winter, for camouflage. But tadpoles also turn white in the dark, or under the influence of melatonin, and the biological meaning of that isn't so clear. It's possible that being white would reduce their loss of heat through radiation, but I think it is more likely that it relates to an increased ability of weak radiation to penetrate their tissues, rather than being stopped near the surface by the melanin in the skin. The absence of melanin makes them more sensitive to light. Bright light suppresses their melatonin, and makes them turn dark brown or black, and this protects them from bright sunlight.

In the retina, melatonin increases the sensitivity of the cells to dim light. It, along with prolactin, another nocturnal hormone, helps to produce dark adaptation of the eyes.

Melatonin increases the concentration of free fatty acids during the night (John, et al., 1983; John and George, 1976)), so it's interesting that one of the long-chain highly unsaturated fatty acids, DHA (docosahexaenoic acid), also increases the light sensitivity of the retina.

Melatonin lowers body temperature, causes vasoconstriction in the brain, heart, and other organs, and slows reactions. An antagonist to melatonin acts as an antidepressant, reducing "behavioral despair" resulting from stress. (Dubocovich, et al., 1990.) So, in the behavioral sense, melatonin reduces sensitivity, yet it increases the eyes' sensitivity to light, causing them to be injured by light that would otherwise be harmless.

Since a hibernating animal under the influence of melatonin can become very cold, the light-sensitizing function of melatonin is probably related to the biological need to be roused out of the torpor occasionally. (Hibernators apparently have to warm up occasionally to sleep in the ordinary manner.) Melatonin is said to intensify dreaming, which is part of the process of arousal from sleep.

All of the stress-related hormones increase during the night. One of the ways these hormones of darkness act is to increase the sensitivity to light, in a process that is an important adaptation for organisms in dim light. In the night, our ability to see (and respond to) dim light is increased. But dark-adapted eyes are very sensitive to injury by bright light. Light that ordinarily wouldn't harm the eyes, will do serious damage when the eyes are dark adapted.

In thinking about the effects of stress and oxygen deprivation, I read the studies demonstrating that the formation of the oxygen-wasting age pigment, lipofuscin, is increased by estrogen, by

oxygen deprivation (in carp living below the ice, or even in fetuses), by metals such as iron, by x-rays, and by highly unsaturated fats.

Free fatty acids that are mobilized from storage tissues in the night and in the winter also tend to increase with aging, as the ability to tolerate stress decreases. Poor circulation and lipofuscin tend to be associated, in a vicious cycle. This means that the retina becomes easier to injure by light in old age, for some of the same reasons that the infant's retina is susceptible.

The fetus accumulates a very large amount of iron, and it absorbs melatonin from the maternal circulation. Prolactin is sometimes elevated in the newborn. Premature babies are often given extra oxygen, which tends to cause vasoconstriction by displacing carbon dioxide. Melatonin's ability to cause vasoconstriction means that stress makes supplemental oxygen more toxic. Synthetic glucocorticoids are often given to premature babies, adding to the risk of retinal damage.

When the mother has been given iron supplements during pregnancy, along with unsaturated oils in the diet, the baby is likely to be born with a vitamin E deficiency and suppressed thyroid function, increasing the probability that it will be jaundiced, leading to treatment of the jaundice with exposure to very bright light.

Although Yandell Henderson had already, in 1928, explained the need for carbon dioxide to be used with oxygen for resuscitating infants or adults, medical researchers and hospital workers could never accept the idea, probably because of a fundamental misunderstanding of the Henderson-Hasselbalch equation. Animal experiments show that supplemental oxygen, without carbon dioxide, causes vasoconstriction, reducing the tissues' supply of glucose as well as oxygen. In combination with too much light, especially blue light, it damages the retina. At hyperbaric pressure, oxygen causes seizures, as well as damage to the lungs and other tissues.

The contribution of bright light to retinal damage in babies has been denied in several recent publications, and these articles undoubtedly provide useful material for defense lawyers to use when hospitals are sued for causing blindness. One publication based on experiments with kittens concludes that bright light does not harm the newborn's retina, but the comparison is between continuous light and intermittent light, rather than between bright light and dim light. Twelve hours of total darkness, rather than sparing the eye by reducing its exposure to light, would sensitize the eye. The only reason such appalling things can be published is that their conclusions protect the hospitals.

A few good studies of the effect of bright light on the retina, and the fact that dark-skinned people with more protective pigment in their eyes have a lower incidence of retinopathy of prematurity, make it clear that the ordinary laws of physics and chemistry actually do apply to the infant eye.

Light and stress, especially with excess iron, damage the retina when the cells contain too much PUFA, since these fats react with light and free radicals. The nocturnal/stress hormones, especially prolactin and melatonin, make the retina more sensitive to light, and more easily damaged. (It's too much darkness that sets up the problem, since the eyes will adapt to excess light, but darkness increases their sensitivity.)

The use of lasers to operate on eyes produces intense inflammation of the eye, but even at low dose the diffusing light causes retinal/macular damage.

Cytochrome oxidase is one of the enzymes damaged by stress and by blue light, and activated or restored by red light, thyroid, and progesterone. It's a copper enzyme, so it's likely to be damaged by excess iron. It is most active when it is associated with a mitochondrial lipid, cardiolipin, that contains saturated palmitic acid; the substitution of polyunsaturated fats lowers its activity. Mitochondrial function in general is poisoned by the unsaturated fats, especially arachidonic acid and DHA.

Creating a "deficiency" of DHA, even when an oil of known toxicity is used to replace the omega -3 oils, prevents retinal damage from light. Despite evidence of this sort, Mead Johnson is going ahead with the marketing of its baby formula containing added DHA which is industrially extracted from algae. (Although the researchers who claim that DHA is beneficial haven't

answered my letters, a representative of the company that manufactures it did answer my question about the actual composition of the oil, and acknowledged that they don't have any idea what the minor ingredients might be.)

When animals are made "deficient" in all the exogenous polyunsaturated fatty acids, linoleic and arachidonic acid as well as linolenic and DHA, they become remarkably resistant to all sorts of stress and toxins.

The polyunsaturated fats make the lungs more sensitive to excess oxygen or hyperventilation, they make the eyes more sensitive to light, and they make the brain more sensitive to fatigue.

The use of synthetic glucocorticoid hormone is standard in treating very premature babies, although it is known to contribute to eye damage. This is because it is considered necessary to improve the lung function of premature babies with respiratory distress. But there is no clear evidence that it is beneficial for lung function in the long run, and very clear evidence that it damages the brain and other organs. There is widespread agreement regarding the use of the glucocorticoids ***prenatally*** to accelerate lung development in women who seem likely to deliver prematurely. Natural cortisol is a factor that promotes lung development prenatally. But cortisol is also a signal produced by a stressed fetus, that triggers the birth process. Cortisol, or the synthetic glucocorticoid, inhibits progesterone production, and stimulates estrogen production, activating uterine contractions and other processes that terminate the pregnancy.

Apparently, it doesn't occur to many people that administering the glucocorticoid triggers premature birth, creating the problem they are intending to treat.

Recognizing causal connections between premature birth and respiratory distress and retinopathy of prematurity, it would be obvious that the greatest effort should be made to prevent the problems by improving the health of pregnant women. Hospitals, however, are invested in high technology systems for treating these problems, and even though their results are dismal, they can't make money by getting pregnant women to eat enough protein to prevent preeclampsia, which is a major cause of premature birth, or by treating the problems with salt, magnesium, progesterone, thyroid, and aspirin when the women haven't had a good diet.

Historically, preeclampsia has been blamed on the mother's or fetus's "bad genes," and that cultural bias was the setting in which these high technology prenatal and neonatal systems developed. High technology "neonatology" derives from the same ideology that motivated Josef Mengele's genetic research in Auschwitz. The idea of genetic determination is still motivating resistance to reasonable preventive approaches.

Thyroid, i.e., T3, is very effective in accelerating lung development in the fetus, and it doesn't have any of the harmful effects of the synthetic glucocorticoids. It normalizes the hormones, increasing progesterone and decreasing estrogen, which are needed for full-term gestation, the opposite of the glucocorticoids' effects. While the cortisol-like drugs damage the brain and other organs, thyroid and progesterone protect them.

Old organisms, like newborns, are easily injured by all sorts of inappropriate excitation. As in premature babies, the aged eyes, lungs, and brain are especially sensitive to damage by stress. *But all organs are subject to the same kinds of damage.* Medical treatments for respiratory distress and macular degeneration in old people are often the same as those used so inappropriately for babies. ***The good health practices that can prevent the inflammatory and degenerative diseases can often make it possible for damaged tissues to recover, even in old age.***

The pituitary hormones, especially prolactin and TSH, are pro-inflammatory, and darkness increases TSH along with prolactin, so to compensate for a light deficiency, the pituitary should be well-suppressed by adequate thyroid. Armour thyroid or Thyrolar or Cynoplus, Cytomel, would probably be helpful. (Eye-drops containing T3 might be a way to restore metabolic activity more quickly.) Limiting water intake (or using salt generously) helps to inhibit prolactin secretion. The saturated fats protect against the body's stored PUFA, and keeping the blood sugar up keeps the stored fats from being mobilized. Aspirin (or indomethacin) is generally protective

to the retina, analogously to its protection against sunburn. Adequate vitamin E is extremely important. There are several prescription drugs that protect against serotonin excess, but thyroid and gelatin (or glycine, as in magnesium glycinate) are protective against the serotonin and melatonin toxicities. Copper and magnesium deficiencies predispose to retinal damage. Red light is protective, blue light (or u.v.) is harmful, so wearing orange lenses would be helpful. Progesterone and pregnenolone, by reducing the stress reactions, should be helpful--in the eye diseases of infancy and old age, as they are in the respiratory distress syndromes.

St. Erik's Eye Hospital, Karolinska Institute, Stockholm, Sweden. **The activity of cytochrome oxidase, outer nuclear layer thickness, and edema were quantitatively evaluated in the blue-light exposed rat retina.** Dark-adapted or cyclic-light reared rats were exposed to blue light with a retinal dose of 380 kJ/m2. Immediately, 1, 2, and 3 day(s) after exposure, the retinas of six rats from each adaptation group were examined. There was no difference between the dark-adapted and cyclic-light reared rats. Immediately after light exposure, cytochrome oxidase activity decreased. The activity in the inner segments remained low at day 1, while severe edema was observed in the inner and outer segments. The outer nuclear layer thickness decreased 1-3 days after exposure. The blue-light exposure inhibited cytochrome oxidase activity and caused retinal injury. Similarity of the injury process in the dark-adapted and cyclic-light reared retinas suggests that rhodopsin was not involved. The inhibition of cytochrome oxidase could be a cause of retinal damage.

Exposure of albino rats to high intensity light results in rapid, graded loss of photoreceptors. The hormonal status and age of an animal at the time of exposure affect the

severity of light-induced retinal damage. The adrenal axis and pituitary hormones (prolactin) have been demonstrated previously to affect the degree of cell death in the retina. Because circadian rhythms for adrenal and pituitary secretion have been demonstrated in the rat, a series of experiments was undertaken to determine if a diurnal pattern of retinal susceptibility to light damage exists which might be related to endogenous endocrine rhythms. Male Sprague-Dawley rats were exposed to 4 hr of high intensity fluorescent light for 8 consecutive days during different phases of the 14:10 hr light: dark animal room light cycle. Morphometric analysis performed at the light microscopic level 2 weeks after exposure demonstrated a differential susceptibility to light-induced cell death depending upon the period during the light-dark cycle when animals received their daily light exposure. Neuronal cell death was confined to the outer nuclear layer as previously described. **The retinas of animals exposed during the middle of the dark period or during the first 5 hr of the light period were significantly more damaged than the retinas of animals exposed during the last 9 hr of the light period.** Control groups for the relative amounts of dark-adaptation between groups suggested that the diurnal susceptibility to light damage was not solely dependent upon the degree of dark adaptation. These results demonstrate a diurnal susceptibility of photoreceptors to light-induced cell death.

The lighting environment of the preterm baby is quite unlike that experienced at any other time of life. Physical and physiological factors control how much light reaches the retina of the preterm baby. With respect to the former, although many neonatal intensive care units are brightly and continuously lit, there is a trend to employ lower levels of illumination and to introduce cycling regimens. Physiological determinants of the retinal light dose include: eyelid opening and transmission, pupil diameter and the transmission characteristics of the ocular media. Early exposure to light does not significantly hasten or retard normal visual development, and it is not a factor in the development of retinopathy of prematurity. However, ambient neonatal intensive care unit illumination may be implicated in some of the more subtle visual pathway sequelae that cannot be attributed to other major complications of preterm birth including altered visual functions and arrested eye growth.

Pediatrics 1992 Apr;89(4 Pt 1):648-53. **Light and retinopathy of prematurity: does retinal location offer a clue?** Fielder AR, Robinson J, Shaw DE, Ng YK, Moseley MJ. Nursery illumination has been implicated in the pathogenesis of retinopathy of prematurity (ROP), although the results of recent studies are conflicting. The data base for this article is a prospective ROP study on 607 infants of birth weight less than or equal to 1700 g including 35 larger siblings from multiple births when 1 infant fulfilled the birth weight criteria. Retinopathy commences preferentially in the nasal retina of the most immature neonate and is less likely to develop, or its onset is delayed, in the superior and inferior **regions. These findings cannot be fully accounted for by regional vascular and neuroanatomical variations. Radiometric and physiological evidence suggests that the very immature neonate, most at risk of developing severe ROP, receives the greatest retinal irradiance. Furthermore, ROP commences in the areas of the retina receiving the highest light dose, and its onset is either retarded or inhibited in the darker retinal regions. Further studies are required to** determine whether early exposure to light is a factor in the development of ROP. If a causal relationship is proven, here at least is one modality that can easily and immediately be controlled.

N Engl J Med 1985 Aug 15;313(7):401-4. **Effect of bright light in the hospital nursery on the incidence of retinopathy of prematurity.** Glass P, Avery GB, Subramanian KN, Keys MP, Sostek AM, Friendly DS. The preterm infant is subjected to prolonged exposure to ambient nursery illumination at levels that have been found to produce retinal damage in animals. We prospectively investigated the effect of exposure to light in two intensive care nurseries by comparing the incidence of retinopathy of prematurity among 74 infants from the standard bright nursery environment (median light level, 60 foot-candles [ftc]) with the incidence among 154 infants of similar birth weight for whom the light levels were reduced (median, 25 ftc). **There was a higher incidence of retinopathy of prematurity in the group of infants who had been exposed to the brighter nursery lights,** particularly in those with birth weights below 1000 g (86 percent vs. 54 per cent, P less than 0.01 by chi-square test). We conclude that the high level of ambient illumination commonly found in the hospital nursery may be one factor contributing to retinopathy of prematurity and that safety standards with regard to current lighting practices should be reassessed.

Endocrinol Exp 1976 Jun;10(2):131-7. **Diurnal variation in the effect of melatonin on plasma and muscle free fatty acid levels in the pigeon.** John TM, George JC. Pigeons maintained on standard diet and held under 12 h daily photo-period in a controlled environmental room, were given intravenous injections of melatonin. A low dose (1.25 mg/kg body weight) of melatonin when given in the middle of the **scotophase, produced a significant increase in plasma FFA when estimated at 20 min and 90 min post-injection, whereas no significant change was seen with injections given in the middle of the photophase. No significant change in muscle FFA level was obtained either during the photophase or the scotophase** when estimated at 90 min postinjection. With a higher dose (5 mg/kg body weight) of melatonin given in the scotophase, on the other hand, a significant increase **in both plasma as well as muscle FFA levels was obtained at 90 min** post-injection but there was no effect on plasma FFA at 20 min or 90 min post-injection in the photophase and at 20 min in the scotophase. It is concluded that melatonin has a lipid mobilizing action in the pigeon when administered during the scotophase.

Arch Int Physiol Biochim 1983 Jul;91(2):115-20. **Diurnal impact of locomotory activity and melatonin and N-acetylserotonin treatment on blood metabolite levels in the rainbow trout.** John TM, Beamish FW, George JC. In rainbow trout forced to swim continuously at sustained speeds for six weeks, selected doses of melatonin or N-acetylserotonin (1.25 and 5.0 mg/kg body weight) injections caused no change in haematocrit. Melatonin did not produce any significant change in plasma glucose level either in the photophase or in the scotophase. However, diurnal variations were observed in the effect of melatonin on plasma free fatty acids (FFA). Melatonin was ineffective in causing **any change in plasma FFA level during photophase but during scotophase, the higher dose (5.0 mg/kg) produced an increase in FFA while the lower dose (1.25 mg/kg) had no effect, N-acetylserotonin administration produced diurnal** variation in its effect on both plasma glucose and FFA. The higher dose of N-acetylserotonin brought about a drop in plasma glucose level during photophase, but both doses were ineffective during scotophase. N-acetylserotonin produced no change in FFA during photophase, but during scotophase tended to lower FFA level. It is suggested that exercise shortens the time required to cause a hypoglycemic effect of N-acetylserotonin during photophase, blocks FFA release-inhibiting action of melatonin observed in photophase, and minimizes the time required for the FFA mobilizing action of melatonin in scotophase.

The paper analyses results after a study of the functional state of pigmented epithelium and the retina in patients with a dry form of senile macular dystrophy as well as of experimental simulation of retinal dystrophy with the help of melatonin and its treatment by taurine. **Melatonin in 10(-3) M concentration leads to development of dystrophic changes** in pigmented epithelium and interacting with it structures, this being testified by remarkable lowering of EOG parameters and electron microscopic findings. Taurine in 10(-3) **M concentration blocks the action of exogenic melatonin as well as has a pronounced positive action on metabolism of dystrophic changes in the pigmented epithelium and photoreceptors. Examination of patients with different stages of a dry form of senile** macular dystrophy revealed statistically significant reduction of KA cEOG at the initial stage of the disease in the presence of normal ERG parameters. In 18% of patients, supernormal values of KA were recorded, that are likely to reflect the presence of "predystrophic hyperactivity" of the pigmented epithelium cells. In progression of the process, the further reduction of electrophysiologic values was recorded. The data obtained speaks about the important role of pigmented epithelium pathology in the pathogenesis of senile macular dystrophy and about high information value of the cEOG method for detection of early stages of the disease. It is believed that disturbances in melatonin metabolism can be one of causes leading to development of retinal dystrophy.

"We studied the effects of prolonged ingestion of melatonin, 1 g per day, on skin color and the serum levels of pituitary hormones in 5 human subjects with hyperpigmented skin. Melatonin lightened hyperpigmented skin of one patient with untreated adrenogenital syndrome, but had no effect on three patients' skin with idiopathic hyperpigmentation and one patient with treated Addison's disease."

Invest Ophthalmol 1976 Oct;15(10):869-72. **Hormonal influences on photoreceptor damage: the pituitary gland and ovaries.** Olafson RP, O'Steen WK. To determine whether the absence of pituitary or ovarian hormones would influence retinal degeneration, female albino rats were either hypophysectomized (HYPEX) or ovariectomized (OVEX) before pubery. Later, they were exposed to continuous light for periods up to 45 days. Retinas evaluated by light microscopic measurements showed damage to the outer nuclear layer (ONL) and photoreceptor layer in both the operated and intact, control rats. However, the degree of damage observed in retinas of HYPEX and OVEX rats was significantly less than that observed in retinas of intact rats exposed to the same lighting conditions. Therefore, hypophysectomy and ovariectomy, which influence the normal development of sexual maturation when performed on immature rats, significantly reduce photoreceptor damage in adult rats exposed to continuous light.

Invest Ophthalmol Vis Sci 1996 Oct;37(11):2243-57. **Retinal light damage in rats with altered levels of rod outer segment docosahexaenoate. Organisciak DT, Darrow RM, Jiang YL, Blanks JC.** PURPOSE: To compare retinal light damage in rats with either normal or reduced levels of rod outer segment (ROS) docosahexaenoic acid. METHODS: Weanling male albino rats were maintained in a weak cyclic light

environment and fed either a nonpurified control diet or a purified diet deficient in the linolenic acid precursor of docosahexaenoic acid (DHA). Half the rats on the deficient diet were given linseed oil, containing more than 50 mol% linolenic acid, once a week to maintain ROS DHA at near normal levels. Diets and linseed oil supplementation were continued for 7 to 12 weeks. To replenish DHA in their ROS, some 10-week-old rats on the deficient diet were given linseed oil three times a week for up to 3 additional weeks. Groups of animals were killed at various times for ROS fatty acid determinations or were exposed to intense green light using intermittent or hyperthermic light treatments. The extent of retinal light damage was determined biochemically by rhodopsin or photoreceptor cell DNA measurements 2 weeks after exposure and morphologically by light and electron microscopy at various times after light treatment. RESULTS: **Rats maintained for 7 to 12 weeks on the linolenic acid-deficient diet had significantly lower levels of DHA** and significantly higher levels of n-6 docosapentaenoic acid (22:5n-6) in their ROS than deficient-diet animals supplemented once a week with linseed oil or those fed the nonpurified control diet. As determined by rhodopsin levels and photoreceptor cell DNA measurements, deficient diet rats **exhibited protection against retinal damage from either intermittent or hyperthermic light exposure. However, the unsaturated fatty acid content of ROS** from all three dietary groups was the same and greater than 60 mol%. In 10 week-old deficient-diet rats given linseed oil three times a week, ROS DHA was unchanged for the first 10 days, whereas 22:5n-6 levels declined by 50%. After 3 weeks of treatment with linseed oil, ROS DHA and 22:5n-6 were nearly the same as in rats supplemented with linseed oil from weaning. The time course of susceptibility to retinal light damage, however, was different. Hyperthermic light damage in rats given linseed oil for only 2 days was the same as for rats always fed the deficient diet. Six days after the start of linseed oil treatment, retinal light damage was the same as in rats given the linseed oil supplement from weaning. Morphologic alterations in ROS of linseed oil-supplemented rats immediately after intermittent light exposure were more extensive than in either the deficient-diet animals or those fed the control diet. The deficient-diet rats also exhibited better preservation of photoreceptor cell nuclei and structure 2 weeks after exposure. CONCLUSIONS: Rats fed a diet deficient in the linolenic acid precursor of DHA are protected against experimental retinal light damage. The relationship between retinal light damage and ROS lipids does not depend on the total unsaturated fatty acid content of ROS; the damage appears to be related to the relative levels of DHA and 22:5n-6.

Invest Ophthalmol Vis Sci 1982 Jan;22(1):1-7. **Antagonistic effects of adrenalectomy and ether/surgical stress on light-induced photoreceptor damage.** O'Steen WK, Donnelly JE. Light-induced damage to retinal photoreceptors in influenced by the endocrine status of the animal during the period of exposure. Experimental manipulation of the pituitary gland and of prolactin levels has been shown to affect retinal damage in rats exposed to visible light. When rats are experimentally stressed, prolactin secretion from the pituitary gland occurs as does secretion of adrenocorticotropic hormone (ACTH), which stimulates the release of adrenal cortical hormones. Since prolactin appears to influence retinal damage and since stressed animals have increased serum levels of prolactin, a comparison of photoreceptor damage in animals in which the adrenal glands were removed or which had been experimentally stressed was undertaken in this study. Adrenalectomized rats had thicker outer nuclear layer (ONL) measurements than those found in sham-operated animals. Stressed rats had severely damaged retinas with cystic degeneration and significantly reduced ONL thickness measurements as compared to retinas of unstressed and adrenalectomized rats. **Therefore hormones of the pituitary-adrenal system appear to be involved in the damage to the retina by light, and this response may be related to an interaction or synergism between the adrenal gland, stress, and prolactin secretion.**

Brain Res 1990 Nov 26;534(1-2):99-105. **Water deprivation protects photoreceptors against light damage.** O'Steen WK, Bare DJ, Tytell M, Morris M, Gower DJ. "Photoreceptor cell death after light-damage and during aging in rats is associated with the hormonal status of the animal, as well as other environmental and intrinsic factors. Restricted caloric intake extends the life of rodents and is usually accompanied by a reduction in water consumption. In this study, male and female rats were placed on restricted water intake for either 3 or 7 days to induce dehydration." "Photoreceptor cells of 7-day, dehydrated male and female rats survived light-damage significantly better than those allowed water ad libitum; however, after 3 days of water restriction, only the male rats demonstrated protection from photodamage." "AVP increased by 350% during the 7-day period of dehydration. Protection of photoreceptors from light-damage in this study may be correlated with osmotically stimulated changes in the retinas of dehydrated animals."

Brain Res 1985 Oct 7;344(2):231-9. **Neuronal damage in the rat retina after chronic stress.** O'Steen WK, Brodish A. Long-term exposure to escapable foot shock has been used to determine if chronic stress influences neuronal cell death in the retina of albino and pigmented rats. Histopathologic and morphometric approaches analyzed changes in photoreceptors and neurons of the bipolar and ganglion cell layers of the retina. Albino Fischer rats when exposed to chronic stress for 4-8 h daily for 1 week to 6 months, developed severe retinal damage, as compared to unstressed control retinas, with reduction in photoreceptor and bipolar neurons, particularly in the superior central retina. The damage was observed in male and female rats, but males appeared to be more susceptible to the influence of stress than female animals. Ganglion cells were unaffected. Photoreceptor destruction did not occur in Long-Evans pigmented rats under identical experimental conditions. The results suggest that: **input of the sensory stimulus, light, to the retina of stressed rats augmented neuronal damage and might be required for its initiation;** and hormones and/or neurotransmitters associated with long-term chronic stress might be related to increased neuronal cell death in the mammalian retina.

Invest Ophthalmol Vis Sci 1977 Oct;16(10):940-6. **Effects of hypophysectomy, pituitary gland homogenates and transplants, and prolactin on photoreceptor destruction.** O'Steen WK, Kraeer SL. "Prepubertal removal of the pituitary gland, which in young animals influences sexual maturation, reduces significantly the amount of retinal photoreceptor destruction when the rats are exposed to continuous illumination in adulthood. When crude pituitary gland homogenate is administered to adult rats hypophysectomized prior to puberty, photoreceptor destruction is more severe. Transplantation of whole pituitary glands to the kidney capsule of hypophysectomized rats also reduces the effect of pituitary gland removal and results in more extensive damage to receptor cells than found in hypophysectomized, adult animals. **Hypophysectomized rats treated with prolactin had more severe retinal damage than untreated, hypophysectomized rats."** "Results of these studies indicate the hormones of the pituitary gland have a regulatory influence on the severity of light-induced, retinal photoreceptor damage in the rat."

Invest Ophthalmol Vis Sci 1992 May;33(6):1894-902. **Melatonin increases photoreceptor susceptibility to light-induced damage.** Wiechmann AF, O'Steen WK. **"Pinealectomy has been shown to protect photoreceptors from light-induced damage, and melatonin treatment has been reported to increase the degree of photoreceptor damage in albino rats."** "The animals that received daily melatonin injections (100 micrograms) in the late afternoon (3 hr before lights off) for 1-3 days before photodamage showed an approximate 30% greater reduction compared with sham control animals in ONL thickness in the superior quadrant, the area most susceptible to light damage. Melatonin injections given after the photodamage did not affect ONL thickness. Although retinal susceptibility to light damage varied with time of day, the degree to which melatonin increased the degree of damage appeared unaffected by the time of day. These results suggest that melatonin may be involved in some aspects of photoreceptor sensitivity to light damage."

Folly is the cloke of knavery

Leakiness, aging, and cancer

A thin layer of fibrin lining blood vessels provides a filtering barrier that helps to strengthen the wall and prevent other proteins from leaking out of the vessels, and it participates in repair processes when the blood vessel is broken.

Cellular energy metabolism is the basis for maintaining the barrier functions. Energy depletion causes the endothelial cells lining blood vessels to become excessively permeable.

When the organism's resistance is low, proteins and fats that normally remain inside the bloodstream can escape into the extracellular matrix and enter cells, contributing to their stress and disorganization, and other materials can escape from cells and enter the bloodstream.

One of the simplest demonstrations of fibrin leakage is to shine a beam of light into the eye; the presence of fibrin and other inappropriate molecules diffuses the light, causing a "flare" in the aqueous compartment (Sawa, 1990). Albumin, a small protein from the blood, is often seen in the urine during stress. The effects of that sort of leakage vary with each organ.

Fibrin is an essential structural and functional part of the organism, but when it escapes from the bloodstream it participates in the degenerative processes of inflammation, fibrosis, and tumor formation. (Its fragments stimulate secretion of inflammatory mediators: Hamaguchi et al., 1991.)

In the hormonal environment dominated by estrogen, mild stresses such as exertion, or even restless sleep, allow toxins (and sometimes bacteria) from the intestine to enter the bloodstream, triggering a complex chain of events that create a systemic inflammatory state. Although these processes have been observed in many simple experiments, their implications are almost always neglected or denied or explained away.

Incorporation of certain polyunsaturated fats into the tissues increases the leakiness of blood vessels, and amplifies the reactions to stresses and inflammatory stimuli.

Antioxidants, thyroid hormone, progesterone, and antiinflammatory agents, including glycine or gelatin, niacin, and saturated fats, can prevent, and in many cases reverse, these degenerative inflammatory processes.

Even a single celled organism has to keep its parts separate, and highly differentiated multicelled organisms have many special systems that serve to keep their parts separate, so the different tissues and organs can maintain their distinct functions.

The movement of substances from blood to cell, and from cell to cell, is normally very tightly controlled, and when the systems that control those movements of water and its solutes are damaged, the tissues' structures and functions are altered. The prevention of inappropriate leakiness can protect against the degenerative processes, and against aging itself, which is, among other things, a state of generalized leakiness.

When cells' energy is depleted, water and various dissolved molecules are allowed to move into the cells, out of the cells, and through or around cells inappropriately. The weakened cells can even permit whole bacteria and similar particles to pass into and out of the blood stream more easily.

One of the earliest investigators of the effects of stress and fatigue on nerves and other cells was A.P. Nasonov, in the first half of the 20th century. A.S. Troshin (1956) has reviewed his work in detail. He showed that in cells as different as algae and nerve cells, fatigue caused them to take up dyes, and that the dyes were extruded, if the cells were able to recover their energy. When nerve cells are excited for a fraction of a second, they take up sodium and calcium, but quickly eliminate them. Prolonged excitation, leading to fatigue, can gradually shift the balance, allowing more substances to enter, and to stay longer.

When nerves or other cells are quickly killed with heavy metals such as osmium, the metals are visible in a layer at the surface, which is sometimes taken as evidence of a "cytoplasmic membrane," but if the cells have suffered oxygen deprivation or have been injured by X-rays, the

metal will be visible as a grey color evenly distributed through the cell. The deposition of the metal occurs when it reacts with electrons. In the relatively vital cell, the heavy metal stops at the surface, and is mostly reduced there, but the devitalized cell presents no structural or chemical barrier to the entry of the metal, and the reactive electrons appear to be evenly distributed through the cell. Oxygen deprivation, X-irradiation, and other stresses cause the cell to be unable to use electrons to produce energy, and instead the electrons are available to react destructively with whatever may be available. While Nasonov showed that dyes and even particles enter energetically depleted cells. newer techniques are able to show that the leaky cells are structurally disrupted by the excessive reduction of their proteins, by excited electrons and free radicals.

In the 1970s, experimenters found that muscles from vitamin E deficient animals released their enzymes when washed in a saline solution, more easily than did the muscles from vitamin E replete animals. Other experiments around the same time showed that reducing the ATP of muscles caused a similar loss of their ability to retain their proteins.

Over the years, many experiments have established. both in vitro and in vivo. that fatigue, stress, aging, and inflammation cause cells to lose their normal constituents, but also to allow foreign materials to enter more easily.

When I was working on my thesis, around 1970, investigating the effects of aging on the metabolism of the uterus, I found that the changes occuring during aging were (in all the ways I tested) the same as those produced by X-irradiation, excess estrogen, oxygen deprivation, excess polyunsaturated fats, and vitamin E deficiency.

Although everyone working in the lab was familiar with the appearance of the uterus from old hamsters (they are typically large, stiff, and somewhat bluish or purplish), everyone was surprised when I suggested that the aged uteri seemed to function as if they were under the influence of a considerable amount of estrogen. Everyone was familiar with the medical textbook doctrine that "menopause is caused by estrogen deficiency." In humans, gynecologists know about "Chadwick's sign," the fact that the uterine cervix turns blue or purple during pregnancy, and everyone knows that blood is blue when it's deprived of oxygen, so it's surprising that estrogen's effect on tissue oxygenation isn't widely recognized.

When estrogen is given to an animal, it almost instantly causes capillaries to become leaky, allowing water to move out of the blood stream, and at the same time, estrogen causes cells to take up water. Both of these processes are the same as the early effects of oxygen deprivation. In the normal reproductive cycle, the surge of estrogen lasts only a few hours, and normal permeability is quickly restored by increasing progesterone. During those intermittent short exposures to estrogen, there isn't usually a massive leakage of serum proteins into the tissues. During the time of estrogenic influence, all kinds of cells are influenced, with the excitatory equilibrium of nerve cells, glandular cells, and immune system cells being shifted, lowering the threshold of excitation, or prolonging the excited state.

Anything that causes inflammation causes a similar loss of water from the blood, as it is taken up by swelling cells. If inflammation is generalized, it causes circulatory shock, because the volume of the blood has become insufficient to serve the organism's needs. One of Hans Selye's earliest observations of the effect of an overdose of estrogen was that it causes shock.

Although water loss causes the blood to become more viscous under the influence of estrogen, the plasma becomes hypotonic, meaning that it contains fewer osmotically active solutes than normal; some of the sodium that helps to maintain the blood's osmotic balance is lost through the kidneys, and some is taken up by the red blood cells and other cells. The osmotic imbalance of the blood causes tissue cells to take up more water, contributing to their increased excitability. In many cases, the vascular leakage of inflammation and shock can be corrected by using osmotically active substances, such as starch solutions, gelatin, or concentrated sodium chloride.

The tissue water retention caused by estrogen, hypoxia, and stress is analogous to the swelling of gels and colloids, that is, it's governed by the state

of the electrons and counter-ions in the system. Excitation, fatigue, or injury can cause a shift of pH toward alkalinity, causing water uptake and swelling.

The blue color of the pregnant cervix, or of the uterus in an animal given an overdose of estrogen, indicates that the tissue isn't sufficiently oxygenated to maintain its normal red color, even though the flow of blood is increased. Some experimenters have noticed that newborn animals sometimes have the postural reflex (lordosis) that indicates an estrogenic state, and that suffocation can produce the same reflex. Irradiating animals with x-rays will also produce the whole range of estrogenic effects.

One of the features of the aged uterus that I studied was the age pigment, lipofuscin, a brown waxy material that accumulates in old or stressed tissues. Prolonged dosage with estrogen accelerates the formation of this pigment, which is largely derived from oxidized polyunsaturated fatty acids. Increased amounts of those fats in the diet, or a deficiency of vitamin E, or exposure to ionizing radiation, or oxygen deprivation, can also accelerate the formation of the age pigment. The presence of the pigment intensifies the effect of estrogen, since the pigment wastes oxygen by functioning as an oxidase enzyme.

Other tests that I did on aged, or estrogenized, uterine tissue indicated that several oxidative systems were activated; for example, the tissues showed an extremely high activity of the enzyme peroxidase, and a very intense reduction of a chemical dye (tetrazolium/formazan) that indicates the presence of reductive and oxidative activity, of the sorts caused by radiation and oxygen deprivation. These reductive and oxidative processes include the production of some free radicals that are capable of reacting randomly with polyunsaturated fatty acids.

The interactions between estrogen and the polyunsaturated fats are now coming to be more widely recognized as important factors in the inflammatory/hyperpermeable conditions that contribute to the development of heart and blood vessel disease, hypertension, cancer, autoimmune diseases, dementia, and other less common degenerative conditions.

Estrogen increases lipid peroxidation, and maintains a chronically high circulating level of free fatty acids, mainly PUFA, activates the phospholipases that release arachidonic acid from cells leading to formation of prostaglandins and isoprostanes, and increases the enzymes that form the inflammation-promoting platelet activating factor (PAF) while suppressing the enzymes that destroy it, and increases a broad range of other inflammatory mediators, interleukins, and NF-kappa B.

The leakage of enzymes out of cells and into the blood stream is recognized medically as evidence of damage to the organ that is losing them. Different combinations of enzymes are commonly considered to be evidence of a heart attack, or skeletal muscle damage, or liver disease, pancreatitis, prostate cancer, etc. But often the reason for the leakage isn't understood. Hypothyroidism, for example, causes leakage of enzymes, possibly mainly from the liver, but also from other organs. Excess estrogen, intense exercise, starvation, anything that increases lipid peroxidation and free radical production, such as drinking alcohol when the tissues contain polyunsaturated fats, can cause organs such as heart and liver to leak their components.

The loss of enzymes increases the energy needed to stay alive, but it doesn't necessarily change the basic functions of the cell. (Though when mitochondrial enzymes leak out into the cytoplasm, the cell's energy metabolism is impaired, at least temporarily.) But the entry of catalytic materials from other tissues changes the organization of a cell, giving it conflicting instructions. In many situations, as L.V. Polezhaev and V. Filatov demonstrated, the substances released during stress and degeneration serve to stimulate healing and regeneration. But when the resources aren't available for full repair or regeneration, only a scar, or atrophic fibrosis, or a tumor will be formed.

In severe stress, intracellular fibrin deposits have been found in the heart (Buja, et al., 1976) and other organs, including the prostate gland. Deficiency of testosterone causes vascular leakage into the prostate. Fibrin promotes tumor growth, partly by serving as a matrix, partly by releasing

stimulatory peptides. Estrogen and prolactin contribute to the edema of the prostate resulting from the absence of testosterone.

Kidney disease, diabetes, pregnancy toxemia and retinal degeneration are probably the best known problems involving vascular leakage, but increasingly, cancer and heart disease are being recognized as consequences of prolonged permeability defects. Congestive heart failure and pulmonary hypertension commonly cause leakage of fluid into the lungs, and shock of any sort causes the lung to get "wet," a waterlogged condition called "shock lung." Simply hyperventilating for a couple of minutes will increase leakage from the blood into the lungs; hyperventilation decreases carbon dioxide, and increases serotonin and histamine. Hyperoxia itself contributes to lung injury, and exacerbates emphysema, though it is common to see patients breathing a high concentration of oxygen. Emphysema (which can be caused by hypothyroidism or hyper-estrogenism, and often can be cured by thyroid or progesterone) and many other respiratory problems are associated with capillary leakage. Cells of the lung and intestine are able to synthesize their own fibrin, apparently because of their special problems in preventing leakage. Prolonged systemic inflammation can lead to lung fibrosis, and fibrosis increases the likelihood of lung cancer.

The inflammatory state that causes exaggerated cellular permeability is very closely related to "hyperventilation," the loss of too much carbon dioxide. The release of serotonin during hyperventilation isn't the only cause of vascular leakage; the carbon dioxide itself is an essential factor in regulating the state of cellular electrons and in maintaining cellular integrity. Hyperventilation, like the shift from oxidative to glycolytic energy production that typifies estrogenized or stressed cells or cancer, raises intracellular pH. In the case of mast cells, increasing alkalinity causes them to release histamine (Alfonso, et al., 2005), but similar "alkaline-induced exocytosis" seems to occur in all stressed tissues.

Since histamine is formed by decarboxylation of histidine, the presence of carbon dioxide in a cell would tend to restrain the reaction, by mass action. All types of cell, at least in animals, form histamine as they are being killed. Sensory nerves in the carotid body respond to hypoxia in the artery supplying the brain by sending signals that accelerate breathing; recent information suggests that it is the formation of histamine in the carotid body that responds to oxygen deprivation (Koerner, et al., 2003). When the formation of histamine is inhibited by blocking histidine decarboxylase, it can slow the rate of breathing (Izumizaki, et al., 2000).

The blood platelets that become incontinent and leak serotonin in the absence of carbon dioxide are undergoing the same structural stresses experienced by endothelial cells, smooth muscle cells, mast cells and all other cells when carbon dioxide is depleted. Although it has been about 70 years since Yandell Henderson made it clear that supplemental oxygen should be combined with carbon dioxide, mechanical ventilation in hospitals is still causing lung injury resulting from hyperventilation, i.e., the absence of carbon dioxide.

A similar misunderstanding of biology was involved in the use of dialysis to treat kidney disease. Until recently, commercial dialysis fluids contained acetate and/or racemic lactate instead of bicarbonate, because of the difficulty of preparing bicarbonate solutions, and the result was that very prolonged dialysis would damage the brain and other organs. (Veech and Gitomer, 1988, Veech and Fowler, 1987.) Dialysis has been seen to increase lung permeability (Bell, et al., 1988).

Amyloidosis produced by chronic dialysis affects all organs, but its effects are best known in the brain, heart, kidneys, and lungs. Serum amyloid-A is one of the acute phase proteins, like C-reactive protein (CRP), that are produced by inflammation. Estrogen, radiation and other stresses increase those pro-inflammatory acute phase proteins, and decrease protective albumin, which is called a "negative acute phase protein," since it decreases when the other acute phase proteins increase. The liver is the major source of the acute phase proteins, and it is constantly burdened by toxins absorbed from the bowel; disinfection of the bowel is known to accelerate recovery from stress.

Seen from the perspective of the stress-leakage syndrome, any serious injury or sickness damages all organs.

The exhaled breath is being used to diagnose inflammatory lung disease, since so many of the mediators of inflammation are volatile, but systemic diseases such as cancer and arthritis, and relatively minor stress can be detected by changes in the chemicals found in the breath. Polyunsaturated fats and their breakdown products--aldehydes, prostaglandins, isoprostanes, hydrocarbons, and free radicals--and carbon monoxide, nitric oxide, nitrite, and hydrogen peroxide are increased in the breath by most stresses.

Both proline and glycine (which are major amino acids in gelatin) are very protective for the liver, increasing albumin, and stopping oxidative damage.

Saturated fats are protective against free radical damage and can reverse liver fibrosis.

Thyroid hormone protects against excess estrogen, and can prevent or reverse fibrosis of the heart (Yao, et al., 1992). It's the main regulator of energy production and tissue integrity.

Antiestrogens are widely effective against vascular leakage. Thyroid, progesterone, and testosterone are among the most effective natural antiestrogens, and they are curative in many conditions that involve vascular leakage. Progesterone and pregnenolone have been called the antifibromatic steroids, and progesterone has been used to treat many inflammatory and fibrotic diseases, including cancer.

The antiserotonin drugs are being increasingly used to treat fibrotic diseases, and other problems related to vascular leakage. The antiserotonin drugs lower prolactin secretion, and prolactin is closely associated with estrogen in causing vascular leakage. Vitamin D, magnesium, and calcium (Graham, et al., 1990; Chen and Ruan, 1995; Chen et al., 1994) can reduce capillary permeability, possibly by reducing parathyroid hormone and mast cell products including serotonin.

Antiinflammatory and anticoagulant things, especially aspirin and vitamin E, protect against the accelerated turnover of fibrinogen/fibrin caused by estrogen and the various inflammatory states.

Since polyunsaturated fatty acids become integrated into all types of cell, and cause so many types of damage when they are released, everything which inhibits their release is protective. Niacinamide, Benadryl, aspirin (Yu, et al., 2003), and procaine help to reduce the release of free fatty acids. Although many studies have demonstrated antiaging, antiinflammatory, and anticancer effects of procaine, its therapeutic use has never been widely accepted, because it didn't fit into traditional ideas of "rational drug therapy." It normalized too many systems to seem "rational." Since people and animals clearly felt better when they were given procaine, an attempt was made to ascribe its action to its slight stimulating action as an inhibitor of MAO, but its main actions probably include antihistamine and anticholinergic effects and inhibition of phospholipases and other lipolytic enzymes (e.g., Chen, et la., 2002; D'Costa and Angel, 1975). Belladonna and atropine have some of those same antiinflammatory effects.

Although fish oil interferes with prostaglandin synthesis, it can contribute to the formation of PAF (Triggiani, et al., 1990), and other mediators of inflammation, energy suppression, and free radicals, including nitric oxide (Nishimura, et al., 2000; Hirafuji, et al., 2002). Since the fish oils are commonly studied by comparing the supplemented animals with "control" animals receiving soy oil, corn oil, or safflower oil, which are strongly pro-inflammatory and broadly toxic, it isn't surprising that their effects usually seem favorable. But when they are compared with saturated fats (as I mentioned in the "Fats and degeneration" newsletter) or with a fat free diet, their effects are seen to be pro-inflammatory and toxic.

Adrenaline, like estrogen, increases lipolysis and free fatty acids in the bloodstream, so keeping adrenaline low most of the time (especially at night) helps to minimize inflammation and vascular leakiness. Hypothyroidism, and the associated hypoglycemia, contribute to the formation of adrenaline, and the thyroid stimulating hormone itself, even if thyroxine and T3 seem normal, can contribute to production of the major

inflammatory mediators. Antihistamines help to prevent excessive adrenaline action.

Although caffeine, if it's combined with hypoglycemia and stress, will increase lipolysis and free fatty acids, several of the methylxanthines, including caffeine, theophylline, and pentoxifylline, can protect against capillary leakage, probably by a variety of antiinflammatory actions, including inhibition of nitric oxide synthesis (Bereta, et al., 1994).

In general, the effects are better when several of the protective agents are used together, since they protect against leakage by many different mechanisms.

Endocrinology. 1999 Apr;140(4):1920-6. **Early effects of castration on the vascular system of the rat ventral prostate gland.** Shabisgh A, Tanji N, D'Agati V, Burchardt M, Rubin M, Goluboff ET, Heitjan D, Kiss A, Buttyan R. Recent studies have found that blood flow to the rat ventral prostate gland is drastically reduced at an early time after castration. These observations caused us to reevaluate the effects of castration on the various cell populations of the ventral prostate, especially those in the prostatic vascular system. Sections of ventral prostate glands obtained at different times after castration were analyzed using the TUNEL (terminal deoxynucleotide transferase-mediated dUTP nick END labeling) staining method to quantify apoptosis in different cell types. The results of this analysis showed a significant increase in TUNEL staining of prostate endothelial and (nonendothelial) stromal cells as early as 12 h postcastration that continued to 24 h after castration. In contrast, TUNEL labeling of prostate epithelial cells was not significantly increased compared with control values until 72 h after castration. The use of dual immunohistochemical staining procedures (anti-CD31 for endothelial cells or antismooth muscle actin for smooth muscle cells combined with TUNEL labeling) allowed us to confirm that the TUNEL-positive vascular cells at these early times after castration were endothelial in nature, whereas smooth muscle cells surrounding the prostate glands or portions of the afferent vascular endothelium were rarely TUNEL labeled. Electron microscopic evaluation of ventral prostate tissues at 48 h after castration provided further morphological evidence for the occurrence of apoptosis in prostate endothelial cells.

Finally, the Lendrum-Fraser histochemical procedure used to identify fibrin leakage in tissues with vascular damage was applied to sections of the ventral prostate gland. This stain revealed diffuse fibrin accumulation in periglandular areas outside the capillaries and blood vessels in prostates from 24-h castrated rats, but not in prostates of sham-operated rats. Our results confirm an early effect of castration on the vascular system of the rat ventral prostate identified by increased apoptosis of endothelial cells and vascular leakiness. As these changes temporally precede the loss of epithelial cells, we propose that they may be causal rather than incidental to regression of the rat ventral prostate after castration.

Thyroiditis. Some confusions and causes of "autoimmune diseases"

Girls' thyroid glands usually enlarge during puberty, and in pregnancy it's entirely normal for the gland to enlarge and to become more active. Eighty years ago, when iodine deficiency was more common in the US and Europe, the idea of a "colloid goiter" was common. In certain regions, many people had enlarged thyroids that contained a large amount of colloid--colloid is the viscous protein (thyroglobulin) solution formed in tiny compartments in the thyroid gland, which can be broken down by "digestive" (proteolytic) enzymes of the cells that have secreted it, forming the thyroid hormones, and allowing them to be released into the blood stream. The hormones are formed as the accumulated protein is broken down; the hormone itself isn't stored in the gland.

The reason for the enlargement of the gland during puberty and in pregnancy, and during some kinds of stress, is that the colloid is formed faster than it is digested by the thyroid gland and secreted into the blood. If something, such as an excess of estrogen, is blocking the production of the thyroid hormone, the gland is likely to enlarge, because the pituitary secretes more thyroid stimulating hormone (TSH) when there is a deficiency of thyroid hormone.

In vitro experiments show that estrogen activates the formation of the colloid, but inhibits its breakdown into the hormones. Progesterone, on the other hand, activates the process of proteolytic digestion and so increases the release of hormones from the gland, decreasing the accumulation of the colloid.

Therefore, when progesterone is deficient or estrogen is present in excess, the colloid tends to accumulate (even to the point of causing a visible enlargement of the gland, a "colloid goiter"), at the same time that the person may be hypothyroid, because the hormone isn't being released from the stored colloid, into the blood stream. But, largely because no one wants to suggest that estrogen can

Injury to the thyroid apparently precedes the development of "autoimmune thyroiditis." There is evidence that tissue injury precedes the appearance of "autoantibodies" in other conditions, too.

Many people with metabolic problems, including hypothyroidism, are being told that they have "a genetic disease." This belief encourages both physicians and their customers to commit themselves to inappropriate treatments, and to misinterpret the results of tests.

Eating seaweed or other foods or supplements containing iodine can cause both hypothyroidism and thyroiditis. The iodate sometimes used as an oxidizing agent in breads have probably contributed to thyroid disease in the industrialized countries.

Dental x-rays, which can cause cancer of the thyroid, brain, and eye, certainly have increased the incidence of thyroiditis and hypothyroidism. The radioactive isotopes that are often foolishly used for supposedly "diagnostic" purposes probably contribute to the incidence and severity of hypothyroidism and thyroiditis.

Besides iodine, radioactive isotopes, and x-rays, other environmental toxins, including mercury and dioxins can cause thyroiditis, but diet and estrogens are probably the causes of most thyroid problems.

A generalized inflammatory state, rather than specific "autoimmunity," is responsible for thyroiditis and other "autoimmune degenerative" diseases.

A "respiratory defect" is behind the inflammatory condition.

Correcting a thyroid deficiency tends to gradually normalize the antibodies.

be pathogenic, an enlarged thyroid gland is now likely to be diagnosed as "Hashimoto's thyroiditis" (or Hashimoto's struma, or goiter, or disease).

Hashimoto's disease is clearly defined as the infiltration of the gland with lymphocytes, "causing destruction" of the gland's active tissue and leading to hypothyroidism. The only way to know that the gland is being invaded by large numbers of lymphocytes is by biopsy, but the condition is normally diagnosed by pure guesswork, without any biopsy. Sometimes "antithyroid antibodies" found in the blood are used to diagnose Hashimoto's disease, but the presence of those antibodies in the blood doesn't mean that they originated in the thyroid gland, and even though they have very specific names (e.g., "antithyroglobulin," "antithyroperoxidase") related to the thyroid gland, they aren't even specific for the thyroid gland. It has been suggested that similarities in molecular structure between thyroglobulin and connective tissue proteins could account for the finding of "antithyroid antibodies" **more frequently in rheumatoid arthritis and Sjogren's syndrome than in Hashimoto's disease and Graves' disease** (Ruggeri, et al, 2002).

In the last 60 years, most of estrogen's toxic effects have been hushed up by the drug industry, and estrogen's central antirespiratory and antithyroid actions are unknown to most contemporary endocrinologists. But endocrinologists often do know that estrogen causes the thymus gland to atrophy, and that the thymus gland is intimately involved in maintaining normal immune functions.

The degenerating thymus gland undergoes invasion by lymphocytes and the replacement of active tissue by fibrous tissue, under the influence of estrogen or stress. The process of cellular invasion in the thyroid gland probably develops more slowly than that in the thymus, because estrogen's effect on the thymus is very rapid.

The cells that make up the thymus are extremely varied, but a large portion of them are able to phagocytize other cells. This self-phagocytosis probably contributes to the gland's ability to shrink with such great rapidity. When other organs are damaged, the removal of debris can be delayed for days, as phagocytic cells gradually enter the tissues from the blood stream.

Hypothyroidism is an important cause of thymic atrophy, and a thyroid supplement can stimulate regeneration of the thymus.

This correction of the thymic portion of the "immune system" by the thyroid hormone is probably involved in the observation that the "antithyroid" autoantibodies decrease under the influence of supplemental thyroid hormone, but the supplement also affects the thyroid gland, by decreasing the thyroid stimulating hormone, TSH. Excess production of TSH causes an inflammation-like stress, that contributes to the production of the colloid goiter and eventually to disordered structural changes in the thyroid gland. A more efficient production and use of thyroglobulin will decrease the tendency of the overstimulated gland to produce a defective globulin that is antigenic.

So, rather than ignoring the frequency of the simple colloid goiter and calling everything "Hashimoto's autoimmune thyroiditis," if we look at the mechanisms involved in the production of autoantibodies, we will tend to see "thyroiditis" as, usually, the last stage in the development of a simple colloid goiter. The autoantibodies, in a healthy person, are probably part of a corrective repair process, rather than a simply pathogenic factor.

There is an almost obligatory medical genuflection toward "genetic causation" of disease, and especially of thyroid disease, autoimmune disease, and other chronic or degenerative diseases. **The fact that thyroid disease and autoimmune diseases are from five to ten times more frequent in women than in men somehow hasn't increased medical interest in the pathogenic role of estrogen,** and it doesn't prevent platoons of medical researchers from making claims to have discovered "which chromosome carries the disease."

This medical bias means that even the physicians who recognize that hypothyroidism is a condition that should be corrected are not likely to believe that it is important to modify the treatment according to changes in the patient's condition. Many doctors assume that a person never recovers

Part of the problem, Lewontin points out, is the casual way in which geneticists speak. "This is seen even in the naming of genes," he notes. "Geneticists speak casually of the 'gene for white eyes', but of course, there is no such gene. There is a variety of genes whose reading by the cell is proximally involved in the production of eye pigment and its deposition in the eye cells." He points out that genes are said to be "self-replicating," engaged in "gene action", "make" proteins and are "turned on " or "off" by regulatory DNA. "But none of this is true... DNA is among the most inert and non-reactive of organic molecules," he writes. S.W. Samuels, in Genes, Ethics & Environment!, an internet public policy journal.Vol.1, No. 1 October, 2000

from thyroiditis, but the evidence is clear that simply giving supplementary thyroid usually gradually corrects the problem. If other protective measures are taken, recovery will be quicker and more complete. When the diet is optimal, the TSH is likely to be "abnormally low," below 1.0 on the standard scale, even without use of a thyroid supplement. Keeping the level of TSH low contributes to the reduction of the generalized inflammatory state that characterizes hypothyroidism and autoimmunity. TSH should be considered to be one of the stress-related pro-inflammatory anti-respiratory hormones, along with serotonin, histamine, estrogen, parathyroid hormone, and prolactin.

The diet should be relatively free of antithyroid foods, especially legumes and polyunsaturated fats, and the foods of the cabbage family, such as broccoli, should be well cooked, and used no more often than once a week. The polyunsaturated fats interfere with the thyroid hormone, disturb the thymus and other immune functions, and increase the antigenicity of tissues.

A high protein diet, of about 100 grams of good protein daily, is protective, and protein deficiency is a common cause of hypothyroidism. But too much emphasis on the muscle meats, including fish fillets, chicken breast or legs, and the usual steaks and chops, can be antithyroid by providing too much tryptophan. That can be offset by using gelatin liberally (chicken soup and ox-tail soup contain lots of gelatin from the bones and connective tissues), because gelatin contains no tryptophan. Whey, which is sold as a protein supplement, and egg whites contain too much tryptophan, and can be antithyroid if used excessively.

Using large amounts of seaweed can cause hypothyroidism and can injure the thyroid cells, contributing to thyroiditis. Seaweed and other iodine-containing food supplements are often sold to improve thyroid function, but they usually have the opposite effect. An iodine deficiency used to cause goiters in some regions, but in the last 50 years most people in the US and Europe have been getting an excessive amount of iodine.

"We can recall when a TSH of 7.0 or below was considered normal. Years later, the TSH cutoff was 6.4, meaning that anything below that level was considered normal. Still later, the cutoff was moved to 5.5. Now, some labs are reporting a level of 4.2 as being the cutoff level, above which the patient may be hypothyroid." "...at our clinic, a TSH over 3 is considered suspicious...." (p. 75)

"Some doctors prefer the lower limit of a corrected TSH to be 1.0. Others are comfortable with a TSH of 0.5. Some thyroid specialists at the Universtiy of California Medical Center in San Francisco like to see the corrected level around 0.2 (slightly below the normal range of 0.4-5.0). That figure is generally considered by many nonuniversity doctors to be too low, suggesting to them that the patient is on too much thyroid medication.

"At our clinic, we have patients who do not feel well until they take enough medication to lower their TSH level to 0.1." (Page 79) R.L. Shames and K.H. Shames, *Thyroid Power,* 2001.

Endotoxin or other material absorbed from intestinal bacteria contributes to a variety of autoimmune problems, including thyroiditis (Penhale and Young, 1988). Combining an indigestible fiber, such as raw carrot, with mild germicides, such as vinegar and coconut oil, can improve the hormonal environment, while reducing the immunological burden.

Adequate light is another important factor in maintaining a high energy respiratory state and preventing the whole complex of inflammatory, autoimmune, degenerative diseases.

(beta-APP) is expressed, proteolytically cleaved and released into the extracellular space in a TSH-dependent fashion."

Lab Invest 1995 May;72(5):513-23. **Localization and regulated release of Alzheimer amyloid precursor-like protein in thyrocytes.** Graebert KS, Lemansky P, Kehle T, Herzog V. "Dysregulation in the processing of the Alzheimer precursor protein (APP) is thought to be central to the deposition of the beta-A4 peptide and to the pathogenesis of Alzheimer's disease. Expression and release of APP has also been known to mediate cell-matrix interactions and to participate in the regulation of cell proliferation." "Because of the specific processing of exportable proteins, thyrocytes represent a particularly useful cell type for the study of the processing of APP/APLP (especially proteolysis and iodination) as an indication of cell surface expression and for the study of the regulation of these functions." "The observations show the expression, maturation, and secretion of APP/APLP in **thyrocytes and the up-regulation of these processes by TSH.** Part of the immature APP/APLP appeared on the cell surface as indicated by its iodination. Apparently, this portion of immature APP/APLP escaped maturation during its transport to the cell surface."

Rinsho Shinkeigaku 1993 Sep;33(9):995-7. **[A case of Hashimoto's encephalopathy with a relapsing course related to menstrual cycle]** [Article in Japanese] Ishii K, Hayashi A, Tamaoka A, Mizusawa H, Shoji S. "Hashimoto's thyroiditis was diagnosed on the basis of high thyroid microsomal titer and mild hypothyroidism. Neurological findings in admission included action tremor in both hands, myoclonus in all extremities, cerebellar ataxia, confusion, and hyperreflexia." "Hashimoto's encephalopathy was diagnosed from these findings. These episodes of remission and exacerbation were observed during the admission. **Her symptoms started at ovulation, worsened during the luteal phase, and improved when menstruation started. After the third relapse, she was treated with oral thyroxine for hypothyroidism and with an estrogen and progesterone combination to regulate the menstrual cycle.** Her thyroid function gradually became euthyroid and she did not experience any subsequent relapses. **The relation between the relapsing course and menstrual cycle suggests that the periodic alteration of gonadotrophic and/or gonadal hormones or the menstrual regulating center itself in the brain may be an important factor of pathogenetic mechanism of the disorder."**

J Clin Endocrinol Metab 1983 Jun;56(6):1164-8., **Thyroid-infiltrating T lymphocyte subsets in Hashimoto's thyroiditis.** Jansson R, Totterman TH, Sallstrom J, Dahlberg PA. "In Hashimoto's thyroiditis, the thyroid gland is infiltrated with immunocompetent lymphocytes." "We observed a relative decrease in intrathyroidal suppressor phenotype T (OKT 8+) cell numbers compared with peripheral blood (13% vs. 26%; P less than 0.01 by Wilcoxon signed rank test). This resulted in an increased helper to suppressor T (OKT 4+/OKT 8+) cell ratio (4.7 vs. 2.1; P less than 0.01). Within the gland, a significant local accumulation of B cells was also registered (27% vs. 12%; P less than 0.01). As to circulating lymphocyte subsets, no differences were found between 18 Hashimoto's thyroiditis patients and 26 normal subjects. Our results are compatible with a local synthesis of thyroid-directed antibodies and emphasize the importance of studying the local immunity in organ-specific autoimmune disease."

Acta Med Austriaca 1999;26(4):126-8. **[Thyroid autoantibodies in depressive disorders]** [Article in German] Konig F, von Hippel C, Petersdorff T, Kaschka W. "We found autoantibodies (MAK, TAK, TRAK) in a high percentage (100 out of 144 = 70%) in severely depressed inpatients. Also we found a Hashimoto thyreoiditis in 5 patients." "We conclude that in cases of repeated depressive episodes especially depression of the elderly and in nonresponders it seems necessary not only to get lab for TSH, T3 and T4 but also to assess the autoimmune status of the thyroid gland (autoantibodies). There is further need for controlled studies whether there is a better outcome in nonresponders to antidepressive medical treatment and positive autoantibody status after supplementation with triiodothyronine."

Hokkaido Igaku Zasshi 1994 May;69(3):614-26. **[Screening for thyroid dysfunction in adults residing in Hokkaido Japan: in relation to urinary iodide concentration and thyroid autoantibodies]** [Article in Japanese] Konno N, Iizuka N, Kawasaki K, Taguchi H, Miura K, Taguchi S, Murakami S, Hagiwara K, Noda Y, Ukawa S. "The prevalence of thyroid dysfunction and its relation to thyroid autoantibodies (TAA) and urinary iodide concentration (UI) was studied in apparently healthy adults in Sapporo (n = 4110) (Sapporo group), and in five coastal areas of Hokkaido (n = 1061) (coastal group) which produce iodine-rich seaweed (kelp). The frequency of above normal UI (high UI) in the morning urinary samples of coastal group was 10.8%, significantly higher than that of Sapporo group (6.4%) ($p < 0.001$). Frequency of positive TAA in both groups were similar. In Sapporo group TAA was positive in 6.4% of males and 13.8% of females with an age-related increase." The overall prevalence of hyperthyroidism (TSH < 0.15 mU/L) in coastal group (0.6%) was similar to that in Sapporo group (1.1%), while that of **hypothyroidism (TSH > 5.0 mU/L) in coastal group (3.8%) was significantly higher than that in Sapporo group (1.3%) (P** < 0.001). The frequency of high UI correlated significantly with that of hypothyroidism with negative TAA ($r = 0.829$, $P < 0.05$), but not with positive TAA, or with that of hyperthyroidism. Hypothyroidism was more prevalent in TAA negative subjects with high UI than with normal UI. Moreover, serum TSH and thyroglobulin levels were higher and free T4 level was lower in former than in latter group. "These results indicate that 1) the prevalence of TAA negative hypothyroidism in iodine sufficient areas may be associated with the amount of iodine ingested, 2) **this hypothyroidism is more prevalent and marked in subjects consuming further excess amounts of iodine,** and 3) excessive intake of iodine should be considered an etiology of hypothyroidism in addition to chronic thyroiditis in these areas."

Endocrinology 1993 Jun;132(6):2645-53. **Thyroglobulin molecules internalized by thyrocytes are sorted in early endosomes and partially recycled back to the follicular lumen.** Kostrouch Z, Bernier-Valentin F, Munari-Silem Y, Rajas F, Rabilloud R, Rousset B. "Thyroglobulin (Tg) molecules stored in thyroid follicle lumens are heterogeneous in terms of iodine and hormone contents. It has been suggested that thyroid hormone is preferentially produced from the most highly iodinated Tg molecules and that thyrocytes are capable of selecting these molecules. The cellular localization as well as the molecular basis of such a selection process are not known." **"In** conclusion, our data show that 1) the thyroid apical endocytic process does not exhibit selectivity for Tg; 2) the thyrocyte possesses a sorting machinery for endocytosed ligands; and 3) internalized Tg molecules can be recycled back to the follicular lumen."

Autoimmunity 1997;26(3):173-87. **Effects of HgCl2 on the expression of autoimmune responses and disease in diabetes-prone (DP) BB rats.** Kosuda LL, Greiner DL, Bigazzi "We found that DP rats treated with mercury or water for a period of 40-125 days developed autoantibodies to thyroglobulin, with a higher incidence in HgCl2-injected animals (92% vs. 56% in

H2O-injected controls). A novel finding of our study was the detection of autoantibodies to laminin in the same rats, again with an increased incidence after HgCl2 treatment (83% vs. 44%)." "... while mercury does not seem to recruit, induce or rescue regulatory T cell function in DP rats, it does stimulate autoantibody responses in these animals."

"Hashimoto's thyroiditis (HT) is the second most common thyroid lesion next to endemic goitre diagnosed on FNA in iodine (I2) deficient areas." "In the present study the patients presented with HT a decade earlier than reported in I2 sufficient areas. Presentation as a nodular thyroid is common. Diagnosis of HT is likely to be missed in smears showing cytological evidence of hyperplasia or abundant colloid. HT was concurrent in 20 cases of endemic goitre."

JAMA 1994 Aug 3;272(5):364-70. **Thyroid diseases among atomic bomb survivors in Nagasaki.** Nagataki S, Shibata Y, Inoue S, Yokoyama N, Izumi M, Shimaoka K. "A significant dose-response relationship was observed for solid nodules, which include cancer, adenoma, adenomatous goiter, and nodules without histological diagnosis, and for antibody-positive spontaneous hypothyroidism (autoimmune hypothyroidism) but not for other diseases. The prevalence of solid nodules showed a monotonic dose-response relationship, yet that of autoimmune hypothyroidism displayed a concave dose-response relationship reaching a maximum (+/- SE) level of 0.7 +/- 0.2 Sv." "The present study confirmed the results of previous studies by showing a significant increase in solid nodules with dose to the thyroid and demonstrated for the first time a significant increase in autoimmune disease among atomic bomb survivors. A concave dose-response relationship indicates the necessity for further studies on the effects of relatively low doses of radiation on thyroid disease."

Int J Radiat Biol 2001 Apr;77(4):475-82. **Persistent subclinical inflammation among A-bomb survivors.** Neriishi K, Nakashima E, Delongchamp RR. "To investigate the associations between inflammation tests and radiation dose in A-bomb survivors." "The associations with radiation dose were statistically significant for leukocyte counts (71.0mm(-3) Gy(-1), p=0.015), erythrocyte sedimentation rate (1.58 mm h(-1) Gy(-1) , p = 0.0001), corrected erythrocyte sedimentation rate (1.14mm h(-1) Gy(-1), p=0.0001), alpha-1 globulin (0.0057 g dl(-1) Gy(-1), p=0.0001), alpha-2 globulin (0.0128 g dl(-1) Gy(-1), p=0.0001), and sialic acid (1.2711 mg dl(-1) Gy(-1), p=0.0001) but not for neutrophil counts (29.9 mm(-3) Gy(-1), p=0.17)." "Among inflammatory diseases, associations were the strongest for chronic thyroiditis and chronic liver diseases." "This study suggests statistically significant association between inflammation in A-bomb survivors and radiation dose of during 1988-1992."

Acta Endocrinol (Copenh) 1978 Aug;88(4):703-12. **A case of Hashimoto's thyroiditis with thyroid immunological abnormality manifested after habitual ingestion of seaweed.** Okamura K, Inoue K, Omae T. "An interesting case of iodide induced goitre with immunological abnormalities is described. The patient who was sensitive to synthetic penicillin had previously been treated for exudative pleuritis, congestive heart failure and acute renal failure. Following recovery, he began to ingest large amounts of seaweed after which he developed goitrous hypothyroidism. It was of interest that the serum level of gamma-globulin increased, and subsequently the antithyroid microsomal antibody became strongly positive, suggesting that thyroidal autoimmune processes had been precipitated. Biopsy of the thyroid gland revealed chronic thyroiditis, with evidence suggesting extreme stimulation by TSH." "While there is evidence suggesting that increased iodide may be an important factor in the initiation of Hashimoto's thyroiditis, this may result from the marked increased sensitivity of Hashimoto's gland to the effects of iodine."

Thyroid 2001 Mar;11(3):249-55. **One-year prophylactic treatment of euthyroid Hashimoto's thyroiditis patients with levothyroxine: is there a benefit?** Padberg S, Heller K, Usadel KH, Schumm-Draeger PM. "After 1 year of therapy with LT4, TPO-Abs and B lymphocytes decreased significantly only in the treated group of euthyroid patients with HT ($p < 0.05$). In contrast, TPO-Abs levels did not change or even increased in untreated euthyroid patients with HT." "Prophylactic treatment of euthyroid patients with HT reduced both serological and cellular markers of autoimmune thyroiditis. Therefore, prophylactic LT4 treatment might be useful to stop the progression or even manifestation of the disease."

Free Radic Biol Med 1999 Oct;27(7-8):901-10. **Thyroid status modulates glycoxidative and lipoxidative modification of tissue Proteins.** Pamplona R, Portero-Otin M, Ruiz C, Bellmunt MJ, Requena JR, Thorpe SR, Baynes JW, Romero M, Lopez-Torres M, Barja G. **"The levels of the glycation product N(epsilon)-fructoselysine (FL) and those of the oxidation products, N(epsilon)-(carboxymethyl)lysine (CML) and malondialdehyde-lysine (MDA-lys), identified by GC/MS in liver proteins, decreased significantly in hyperthyroid rats,** as well as (less acutely) in hypothyroid animals." "Cytosolic proteolytic activity against carboxymethylated foreign proteins measured in vitro was significantly increased in hypo- and hyperthyroidism."

Clin Exp Immunol 1988 May;72(2):288-92. **The influence of the normal microbial flora on the susceptibility of rats to experimental autoimmune thyroiditis.** Penhale WJ, Young PR. "Female PVG/c strain rats maintained under **specific pathogen-free conditions until weaning were found to be significantly less susceptible to the induction of autoimmune thyroiditis by thymectomy and irradiation** than conventionally reared rats of the same strain." "It was found that the oral administration of antibiotics followed by fresh, homogenized, intestinal contents obtained from conventionally reared rats to newly weaned SPF PVG/c rats significantly augmented their autoimmune susceptibility." **"It is proposed that the composition of the normal gastrointestinal flora of conventionally reared rats profoundly influences susceptibility to the induction of autoimmune thyroiditis in this particular experimental model, possibly by antigenic cross-reactivity with thyroid tissue."**

Radiats Biol Radioecol 1996 Jul-Aug;36(4):632-40. **[The probable sequelae of thyroid damage from radioactive iodine during the Chernobyl accident]** Poverennyi AM, Shinkarkina AP, Vinogradova IuE, Beziaeva GP, Podgorodnichenko VK, Tsyb AF. "The analysis of the situation when children's thyroids were subjected to irradiation shows that tumors can most frequently develop as late as 20-30 years after irradiation. There are reasons to believe that tumors are induced by low dose of irradiation. The most important factor in development of pathologies is for sure the

age of the children of the moment of irradiation. A well-known consequence of the impact of radiation on the thyroid is the lymphocyte thyroiditis."

Clin Immunol Immunopathol 1996 Dec;81(3):287-92. **Iodine-induced autoimmune thyroiditis in NOD-H-2h4 mice.** Rasooly L, Burek CL, Rose NR. "Excess iodine ingestion has been implicated in induction and exacerbation of autoimmune thyroiditis in human populations and animal models." "Levels of serum thyroxin (T4) were similar in the treatment and control groups. Thyroglobulin-specific antibodies were present in the iodine-treated group after 8 weeks of treatment but antibodies to thyroid peroxidase were not apparent in the serum of any of the animals. Levels of thyroglobulin antibodies increased throughout the 8-week iodine ingestion period; however, no correlation was seen between the levels of total thyroglobulin antibodies and the degree of thyroid infiltration at the time of autopsy."

J Endocrinol Invest 2002 May;25(5):447-54. **Thyroid hormone autoantibodies in primary Sjogren syndrome and rheumatoid arthritis are more prevalent than in autoimmune thyroid disease, becoming progressively more frequent in these diseases.** Ruggeri RM, Galletti M, Mandolfino MG, Aragona P, Bartolone S, Giorgianni G, Alesci D, Trimarchi F, Benvenga S. **"To verify the greater prevalence of circulating thyroid hormone autoantibodies (THAb) in primary Sjogren syndrome (SS) vs Hashimoto's thyroiditis (HT) and Graves' disease (GD),** we measured THAb in the serum of patients with these 3 diseases who were sampled from 1998-1999 (no.=20, 88, 25) and 1990-1992 (no.=13, 75, 31)." "We found that IgG antibodies against T3, T4 or both were present with these prevalences in the 1975-1982, 1990-1992 and 1998-1999 series: HT=1, 4, 20%; GD=2, 6, 32%; SS=20, 31, 50%; RA=0, 12, 26%; other collagenoses=0, 0, 0%. The majority of the Sjogren or arthritis cases positive for THAb were negative for TGAb, while the opposite was true for the 2 autoimmune thyroid diseases. We conclude that prevalence of THAb in the 2 non-thyroid autoimmune diseases is greater than in the 2 thyroid autoimmune diseases. In addition, prevalence of THAb is increasing over time regardless of disease. **Molecular similarity between extra-thyroid connective proteins (specifically associated to primary SS and RA) and iodinated regions of TG,** and an increased preponderance of environmental factors as triggers of autoimmune diseases might account for our findings."

Endocrinol Metab Clin North Am 1987 Jun;16(2):327-42. **Environmental factors affecting autoimmune thyroid disease.** Safran M, Paul TL, Roti E, Braverman LE. "Exposure to excess iodine, certain drugs, infectious agents and pollutants, and stress have all been implicated."

J Immunol 1994 Mar 1;152(5):2586-95. **Ionizing radiation and autoimmunity. Induction of autoimmune disease in mice by high dose fractionated total lymphoid irradiation and its prevention by inoculating normal T cells.** Sakaguchi N, Miyai K, Sakaguchi S. "Ionizing radiation can functionally alter the immune system and break self-tolerance."

J Clin Endocrinol Metab 1995 Dec;80(12):3513-9. **Thyroid epithelial cells produce large amounts of the Alzheimer beta-amyloid precursor protein (APP) and generate potentially amyloidogenic APP fragments.** Schmitt TL, Steiner E, Klingler P, Lassmann H, Grubeck-Loebenstein B. "In view of the known association between familial AD and thyroid autoimmune disease, the expression pattern and cellular processing of APP in human thyroid cells were investigated." "The results of these studies demonstrated that APP isoforms 770 and 751 were expressed in fresh thyroid extracts as well as in cultured thyroid epithelial cells, with APP 770 being the predominant form. Compared to other types of cells, such as lymphocytes and fibroblasts, thyroid epithelial cells produced larger amounts of APP." "Interestingly, thyroid epithelial cells also contained larger C-terminal APP fragments of 21, 35, and 41 kDa. From the sizes of these fragments it could be deduced that they contained the entire amyloid beta sequence and were thus potentially amyloidogenic. The 41-kDa fragment was unique to thyroid cells. These fragments may be released into the circulation after thyroid cell damage. Increased/altered thyroid APP expression in familiar AD may induce alterations in thyroid epithelial cells and cell damage, and thus explain the frequent occurrence of thyroid autoimmunity in this disease."

Radiats Biol Radioecol 1994 Jan-Feb;34(1):3-7. **[Antibodies to the thyroid microsomal antigen in children and adolescents subjected to radiation exposure as a result of the accident at the Chernobyl Atomic Electric Power Station]** Shinkarkina AP, Podgorodnichenko VK, Poverennyi AM. "There is significant difference in the frequency of the antibody appearance between persons suffered from radioactive iodine and unsuffered ones. Correlation between levels of antimicrosomal antibodies and radiation dose obtained from incorporated radioactive iodine was not estimated."

Verh Dtsch Ges Pathol 1996;80:297-301. **[Spontaneous Hashimoto-like thyroiditis in cats]** Schumm-Draeger PM, Langer F, Caspar G, Rippegather K, Herrmann G, Fortmeyer HP, Usadel KH, Hubner K. "A breeding line of domestic cats spontaneously developing symptoms of hypothyroidism between the 40th and 60th day of life (fur changes, loss of appetite, growth retardation), elevated levels of antibodies against microsomal structures and thyroglobulin, and lymphocytic thyroid infiltration has been recently established at our facility. Aim of our studies was to examine the effect of high iodine ingestion or prophylactic thyroid hormone therapy on functional and morphological characteristics of this Hashimoto-like thyroiditis in cat. From birth to day 80 of life cats were treated with iodine (n = 9; 0.1 mg/l) or thyroxin (n = 13; 2.0 micrograms/ kg/d) respectively. Untreated animals served as controls (n = 12). Cat-serum was tested for thyroid function (TT3, TT4). After 8 weeks the thyroid tissue was submitted to routine histological processing (H&E) and the inflammatory activity was scored." "Both untreated hypothyroid (UHC) as well as iodine-treated (IC) cats revealed a significantly higher degree of thyroid inflammation and higher tissue levels of IgM as the thyroxin-substituted animals (TC)." **"Early thyroid hormone therapy significantly decreases both incidence and activity of autoimmune thyroiditis in cats as measured by inflammatory infiltration, IgM production and epithelial proliferation. Animals with excess iodide intake, however, show an aggravation of the autoimmune inflammatory activity."**

Vnitr Lek 1999 Sep;45(9):527-31. **[Reactions to metals in patients with chronic fatigue and autoimmune endocrinopathy]** Sterzl I, Hrda P, Prochazkova J, Bartova J, Matucha P. "Our study was designed to assess the effect of heavy metals on the severity of fatigue in autoimmune thyroid disease associated with autoantibodies against other endocrine organs." "Fatigue regardless of the underlying disease is primarily associated with hypersensitivity to inorganic and organic mercury, nickel, and gold. The groups differed in their hypersensitivity to other metals. In the control group, hypersensitivity--mostly to cadmium and lead--was found in four of the examined individuals only. Statistical analysis of data obtained from professionals and controls revealed a higher incidence of positivity to organic and inorganic mercury and nickel in professionals."

Neuroendocrinol Lett 1999;20(3-4):221-228. **Mercury and nickel allergy: risk factors in fatigue and autoimmunity.** Sterzl I, Prochazkova J, Hrda P, Bartova J, Matucha P, Stejskal VD. We

have found that fatigue, regardless of the underlying disease, is primarily associated with hypersensitivity to inorganic mercury and nickel. The lymphocyte stimulation by other metals was similar in fatigued and control groups. To evaluate clinical relevance of positive in vitro findings, the replacement of amalgam with metal-free restorations was performed in some of the patients. At a six-month follow-up, patients reported considerably alleviated fatigue and disappearance of many symptoms previously encountered; in parallel, lymphocyte responses to metals decreased as well. We suggest that metal-driven inflammation may affect the hypothalamic-pituitary-adrenal axis (HPA axis) and indirectly trigger psychosomatic multisymptoms characterizing chronic fatigue syndrome, fibromyalgia, and other diseases of unknown etiology.

The New England Journal of Medicine Volume 326:513-518 February 20, 1992 Number 8. **Disappearance of thyrotropin-blocking antibodies and spontaneous recovery from hypothyroidism in autoimmune thyroiditis.** N Takasu, T Yamada, M Takasu, I Komiya, Y Nagasawa, T Asawa, T Shinoda, T Aizawa, and Y Koizumi. "We determined the frequency with which thyrotropin-blocking antibodies were present in 172 hypothyroid patients with goitrous autoimmune thyroiditis (Hashimoto's disease) and 64 hypothyroid patients with atrophic autoimmune thyroiditis (idiopathic primary hypothyroidism). For 6 to 11 years we then followed 21 of these patients who were found to have thyrotropin-blocking antibodies. They received levothyroxine therapy for 3.5 to 8 years, after which it was discontinued." **"Thyrotropin-blocking antibodies were detected in 9 percent of the patients with goitrous autoimmune thyroiditis and in 25 percent of those with atrophic autoimmune thyroiditis. Among the 21 patients studied serially while receiving levothyroxine, thyrotropin-blocking antibodies disappeared in 15 (group 1), 7 of whom had goiter initially, and persisted in 6 (group 2), none of whom had goiter initially.** Levothyroxine therapy was subsequently discontinued in these 21 patients. Six of those in group 1 (four with goiter) remained euthyroid (mean follow-up after discontinuation of therapy, 2.1 years), and nine became hypothyroid again within 3 months. All six patients in group 2 remained hypothyroid. CONCLUSIONS. Hypothyroidism in some patients with autoimmune thyroiditis may be due to thyrotropin-blocking antibodies. The production of thyrotropin-blocking antibodies may subside, producing remissions of hypothyroidism. Chronic autoimmune thyroiditis may therefore cause transient as well as permanent hypothyroidism."

Clin Exp Immunol 1993 Mar;91(3):442-8. **Gender-related influences on the development of chronic graft-versus-host disease-induced experimental lupus nephritis.** Treurniet RA, Bergijk EC, Baelde JJ, De Heer E, Hoedemaeker PJ, Bruijn JA. "Autoimmune diseases are far more common in women than in men. **In the incidence of systemic lupus erythematosus (SLE), the female-to-male ratio is as high as 10:1. This suggests that sex hormones may play a fundamental role in determining the susceptibility to these diseases."** "After four cell transfers, female recipients developed a significantly higher albuminuria than both male groups. Serum concentrations of autoantibodies against glomerular basement membrane (GBM), collagen IV, and laminin were significantly higher in females 2-4 weeks after induction." "These findings indicate that: (i) in this model of lupus nephritis, susceptibility to glomerulonephritis is strongly influenced by sex-related genes; and (ii) among the variety of autoantibodies occurring in this model of SLE, both anti-GBM and anti-RTE autoantibodies play a key role in the pathogenesis of glomerulonephritis."

J Immunol 2002 Mar 1;168(5):2470-4. **A unique combination of inflammatory cytokines enhances apoptosis of thyroid follicular cells and transforms nondestructive to destructive thyroiditis in experimental autoimmune thyroiditis.** Wang SH, Bretz JD, Phelps E, Mezosi E, Arscott PL, Utsugi S, Baker JR Jr. "Compared with control animals, mice treated with IFN-gamma and TNF-alpha showed significantly sustained lymphocytic infiltration in the thyroid, which was associated with the destruction of portions of the follicular architecture at wk 6 after initial immunization." "Minimal apoptosis of thyroid epithelial cells was observed unless the mice were pretreated with IFN-gamma and TNF-alpha. These data demonstrate that this unique combination of inflammatory cytokines facilitates the apoptotic destruction of thyroid follicular cells in experimental autoimmune thyroiditis, in a manner similar to what is observed in Hashimoto's thyroiditis in humans."

Presse Med 2002 Oct 26;31(35):1670-5. **[Hypothyroidism related to excess iodine]** Wemeau JL. "Iodine-induced hypothyroidism is observed in fetuses, newborn, adults and in the elderly. It is observed in individuals without underlying overt thyroid disorder, and specially in patients with autoimmune thyroiditis or those previously treated for thyroid diseases (Graves' disease, subacute or pospartum thyroiditis, iatrogenic thyroid dysfunction...)." "The hormone deficiency is of obvious clinical expression, or sometimes discreet and revealed by hormone exploration. It is usually temporary, regressing with a few days or weeks after iodine withdrawal. Nevertheless, some patients require transient hormone replacement therapy."

Clin Exp Immunol 1982 Apr;48(1):196-200. **Thyroid antibodies are produced by thyroid-derived lymphocytes.** Weetman AP, McGregor AM, Lazarus JH, Hall R. "The significance of the characteristic lymphocytic infiltrate in the target organ in organ-specific autoimmune disease is unknown." **"The thyroid appears to be an important site of thyroglobulin antibody production but the thyroid lymphocytes also contain many** IgG PFCs of non-thyroglobulin specificity."

Nephrol Dial Transplant 1993;8(5):402-6. **Increased prevalence of thyroid peroxidase antibodies (TPO-Ab) in women with Glomerulonephritis.** Westman KW, Erfurth EM, Hagmar L, Bygren PG, Ericsson UB, Landin-Olsson M. "Women with glomerulonephritis had both a significantly greater prevalence of thyroid peroxidase antibodies (odds ratio 3.85, 95% confidence interval 1.04-14.3) and an increased prevalence of elevated serum TSH values (P = 0.007). No such difference was found in men."

Baillieres Clin Rheumatol 1996 May;10(2):259-71. **Hormones and autoimmunity: animal models of arthritis.** Wilder RL. "Hormones, particularly those involved in the hypothalamic-pituitary-gonadal and -adrenal axes (HPG and HPA), play important roles in various animal models of autoimmunity such as systemic lupus erythematosus in mice and collagen-induced arthritis (CIA) in mice and rats, and the streptococcal cell wall, adjuvant and avridine arthritis models in rats. Intimately linked to the subject of hormones and autoimmunity are gender, sex chromosomes and age." **"Oestrogens stimulate higher corticosteroid responses in females. The animal model data have major implications for understanding autoimmunity in humans.** In particular, adrenal and gonadal hormone deficiency is likely to facilitate T-cell dependent diseases like rheumatoid arthritis, while high oestrogen levels or effects, relative to testosterone, are likely to promote B-cell dependent immune-complex-mediated diseases such as lupus nephritis."

November 2001

Some issues related to the stress of winter:

"Winter sickness" occurs when there isn't enough daylight to allow us to recover from nocturnal stress. The stress related hormones rise at night, and winter nights are long.

The inadequate light produces thyroid and progesterone deficiencies.

A progesterone or thyroid deficiency, or estrogen and polyunsaturated fat excess, causes serotonin to increase. Cold, dark, and even minor stresses cause increased serotonin.

The amino acid tryptophan can be metabolized into serotonin, which can be converted into melatonin.

More than twenty years ago, tryptophan was being promoted as a sedative, even though it was known to be the only amino acid that is carcinogenic. In excess, it suppresses the function of the thyroid gland. A protein deficiency releases tryptophan from muscles.

A "serotonin deficiency" was often said to cause depression. Hydroxy tryptophan (5-HTP) is sold as a serotonin precursor that is supposed to improve mood. Many kinds of stress cause serotonin's activity to increase.

Melatonin has been sold as a sleeping pill, longevity pill, and anticancer agent. Its production in the body is stimulated by stress and darkness.

Light, especially red light, penetrates into the body, and suppresses free radical activity and activates the crucial respiratory enzyme, cytochrome oxidase, which is activated by thyroid, and which is inactivated by polyunsaturated fats.

Serotonin released from platelets causes blood clotting and vascular spasms, and stimulates cell division. It and histamine are mediators of inflammation that cause blood vessels to leak.

Serotonin triggers the release of the stress hormones, ACTH, cortisol, and prolactin.

People often gain weight during the winter; in the far north, blood tryptophan is elevated in the winter; depressed women have increased melatonin, alcohol lowers melatonin; alcohol consumption is increased by darkness.

The use of antiserotonin drugs in alleviating stroke, hypertension, heart failure, diabetes, depression, obesity, rheumatoid arthritis, lupus (SLE), fibrosis, wheezing, and migraine suggests the importance of hyperserotonemia in causing disease.

Postpartum, premenstrual, and seasonal serotonin soaks: Hints about aging, insomnia and diabetes

When I read, in the early 1950s, about the cyclical peaks of mortality in the early morning hours and winter months, that had been evident in actuarial tables for a long time, it wasn't hard to accept that light was good for us, and that darkness was harmful. "Chronobiology," the awareness that biological responses are dependent on the time of day, was firmly established by the 1950s.

"...Tryptophan transport was increased in the major depressions and in the dysthymic disorders." D. Pringuey, et al., 1986.

"...We propose that there is a hyperserotonergic state in the hippocampal formation of some subjects with schizophrenia...."
E. Scarr, D.L. Copolov, B. Dean, L. Rebecca.

"...a hyperserotonemic condition has been documented in preeclampsia."
Carrasco, et al., 2000.

"Both melatonin and serotonin were potent inhibitors of progesterone release."
Schaeffer and Sirotkin, 1997.

Beginning in the 1950s, when I would spend the summers working in the woods, I noticed effects of sunlight that I didn't understand, such as the worsening of acne in proportion to the amount of sun exposure, as well as during times of stress. In 1965, I noticed that even incandescent light exposure during the night could immediately provoke my acne, so I realized that ultraviolet irritation wasn't the essential factor. First I thought the eyes' consumption of vitamin A might be responsible, since taking additional vitamin A would control my acne, but then I realized that an

extended photoperiod stimulated the sex hormones, and that this increased demands for vitamin A.

When I moved to the northern US from Mexico in 1965, I began noticing other interesting hormonal and nutritional effects relating to the seasons. In the winter of 1966-67 I began referring to "winter sickness" as the consequence of the hormonal changes produced by a lack of light exposure. Women who moved from a sunny climate to cloudy Eugene, and who often lived in gloomy basement apartments while they were at the university, described premenstrual depression and other symptoms that they had never experienced before. Many serious diseases had their onset during these times of light deprivation and hormonal upset.

I submitted some of my observations on winter sickness to various journals, and didn't get any responses from most of the editors, except for occasional sarcastic remarks about how ridiculous it is to suggest that ***light*** would have biological or psychological effects on humans.

Since 1966 I had been including a discussion of light's effects in my classes on nutrition and hormones and aging, and in the early seventies I began travelling around to talk to health-food, alternative medicine, and church groups, and to talk on occasional radio and television programs, where I would emphasize the importance of good light along with good nutrition. I found that the general public, and especially so-called "conservative" people, were remarkably receptive to ideas of interactions between organism and environment, and between mood and chemistry. I think their receptiveness had to do with the attitude called "paranoia," an attitude that has its positive features, as Salvador Dalí observed.

Professional people, especially journal editors, on the other hand, seemed to suffer from a mental rigidity that was the polar opposite of paranoia, a belief that nothing was happening outside of the set of beliefs residing in their own minds. This is a psychiatric condition that can be called "editorness," or simply "professionalism."

Although no journal or magazine had responded favorably to my articles on winter sickness and light therapy, some of those editors later began publishing similar observations by themselves or others, and by 1985 "Seasonal Affective Disorder" was becoming something like a "movement," with people arguing about the proper use of "light panels" and phase-shifting of melatonin, and even direct supplementation of melatonin. When its factors are reduced to a minimum, usually two, a new thought can sometimes penetrate into the professional mentality, though they are likely to get one or both of those factors wrong, as often as not. The use of bright light to treat depression should have made people realize that a melatonin excess contributed to depression, but that simple idea has been generally evaded.

The reluctance to see any connection between mood and hormones, or between light and health, probably resulted from an education in which there was already an explanation for everything. Now that medicine accepts a role for light and hormones in mood and behavior, it is within a culture dominated by Estrogen Replacement Therapy and Selective Serotonin Reuptake Inhibitors, such as Prozac. When there is a product for everything, explanations are degraded, and professionalism reaches a new low. The use of Prozac and similar drugs to treat PMS is an example of how product-professionalism works. (Its action in PMS is probably the result of increasing a brain steroid, compensating for a progesterone deficiency, exactly contrary to the doctrine that it acts by increasing serotonin availability.)

People who believe that there is a "biological clock" in the brain think that light signals entering through the eye provide the cues that set the clock, and that the brain then organizes the behavior that's appropriate for the season and time of day. But pigeons wearing opaque hoods can sense environmental light if the rest of their body is uncovered. The same sort of bodily sensitivity to light was demonstrated by shining light onto the back of a person's knee.

Instead of a "clock" that consists of some procedure for counting enzyme reactions or DNA oscillations or something of the sort, for which there is not even a clear theory, I think the evidence supports the idea that physiological

states reflect the organism's relation to the environment, and that, in the absence of the necessary amount of light and heat from the environment, energy stores in the form of glycogen become depleted, creating hunger and a variety of stress reactions. It takes some time to deplete glycogen stores, and it takes time to assimilate food, and so hunger and satiation tend to be cyclic, but it isn't productive to call these processes "a biological clock."

Mitochondria change their shape and function during the night, becoming radically less effective at producing energy. Light regenerates the crucial cytochrome oxidase enzyme, creating the energy needed to repair mitochondria. During darkness, glycogen stores in the liver, brain and other tissues are used rapidly, because of the mitochondrial respiratory inefficiency. Fats are mobilized from storage under the influence of adrenalin that rises when glucose is scarce. Rapid eye movement sleep, the phase of active dreaming, increases with hunger, and the arousal subsides cyclically as adrenalin is suppressed by other adjustments, including increased cortisol, melatonin, GABA, and many other regulatory substances and processes.

Light suppresses melatonin and serotonin, but its action is biological and biochemical, not just informational--it's a component of our metabolism, not just a "cue." Our biological rhythms, of approximately 24 hours, do have a learned component, but Frank A. Brown's experiments in the 1960s made it clear that there are important rhythmic environmental influences other than the cycle of light and dark. Brown's biological experiments were complemented by Alexandre Rothen's physical experiments which made it clear that the diurnal cycles aren't just light cues. In the university's hamster house where I worked, the cycles of light and dark were automatically controlled, air temperature was kept constant, and there were no windows, but in the winter the hamsters' thymus glands practically disappeared, and then in the summer they were restored. The infrared and microwave radiation of the environment, that can penetrate walls, must be constant to avoid biological stress.

Winter, at least in some species, causes serotonin to increase. (Philo and Reiter, 1980) In the winter, and in the morning, intraocular pressure (IOP) increases (Qureshi, et al., 1999), and drugs that antagonize serotonin reduce IOP. Women, on average, have higher IOP than men, and estrogen increases IOP (and serotonin).

Serotonin is a mediator of inflammation that suppresses metabolism, disturbs blood pressure, and promotes clotting, so it would be a Manichean-seeming misfortune if it was also essential to have lots of it to experience eupohoria. But in reality a state of "serotonergia" is a state of torpor, discomfort, and depression, rather than a state of alert pleasure. Its levels are above normal in autism, attention deficit disorder, and some forms of mental retardation, as well as in various types of depression.

A mediator of stress transduces an infinite range of harmful influences into a stereotyped response, mobilizing the adaptive antistress systems. A relatively harmless stress, such as overheating, chilling, oxygen deficiency or exertion, can leave the organism stronger as a result of its adaptation, but other kinds of challenge, such as prolonged darkness, leave the organism more vulnerable despite its mobilization of its antistress systems. The difference seems to be that passivity allows a generalized catabolism, while an active response strengthens the functional system that is being challenged. Winter stress is a prolonged passive stress. The passive responses of hibernation, over-eating, lethargy or depression probably represent the best biological response under the circumstances, which have impaired the capacity for energetic response.

Depression, like inflammation, is a costly reaction for an organism that can't achieve a better adaptation. Serotonin is a mediator of both depression and inflammation. On the cellular level, serotonin depresses respiration, and on the organismic level it depresses body temperature which depresses biochemical reactions generally. For mood and mental function, it's probably significant that serotonin depresses blood circulation in the brain (Mendelow, et al., 1977; Eidelman, et al., 1978). There is no question about serotonin's being a mediator of depression, except

for the stereotype that got its start in the 1960s that wants to see it as a sedative euphoriant, a deficiency of which produces many psychological problems. The tryptophan and melatonin industries were built up around this serotonin myth.

Aging and the degenerative diseases involve combinations of metabolic depression and inflammation. Anti-serotonin agents are coming to be recognized as treatments for a wide variety of degenerative diseases.

Minks that have mated in the winter don't implant the fertilized ovum in the uterus until the spring equinox, when progesterone rises suddenly, and allows both the uterus and the embryo to begin the process of pregnancy and gestation. Progesterone provides the oxygen needed for the successful implantation of the embryo, while estrogen and serotonin lower the intrauterine oxygen.

Under good conditions, the (premenstrual) luteal phase of the monthly cycle resembles pregnancy, as a period of progesterone dominance, in which the abundance of progesterone causes cells to decrease their estrogen content. The luteal phase is actually the first stage of pregnancy, and if there is implantation of an embryo all of the processes that begin at ovulation progress continuously until childbirth occurs. When there is no implantation, the luteal phase progesterone dominance is terminated, allowing estrogen to enter tissues and producing menstruation. The sudden decrease of progesterone production before menstruation is similar to the decrease of hormone production just before childbirth. The same conditions that produce the premenstrual syndrome, if they aren't corrected by the placenta's massive production of progesterone, will produce preeclampsia, toxemia of pregnancy, eclampsia, and postpartum depression. They are also related to the problems that become so common at menopause. Whenever the production of progesterone falls, tissues are susceptible to estrogen.

There are several common causes of a progesterone deficiency. Deficiencies of thyroid, vitamin A, and cholesterol are often responsible for a progesterone deficiency. Inadequate light exposure can cause it. Excess polyunsaturated fats, interfering with gonads and thyroid, can cause it. And excess serotonin can cause it.

Serotonin is a precursor of melatonin, which tends to be produced at night. Because of the books published during the intensive marketing campaign for melatonin, many people are familiar with the work of Maestroni and Pierpaoli, who reported that treatment with melatonin, or with the transplantation of pineal glands from young animals, would extend the life span of mice and prevent cancer. Melatonin is often called the "pineal hormone," though there are other hormones in the pineal, and many other tissues can produce melatonin.

Mice and rats are nocturnal animals, so they are notoriously inappropriate for evaluating the nocturnal hormones as they might relate to humans and other animals that are active in the daytime. Although melatonin sometimes antagonizes serotonin in a protective way, in itself it can lower body temperature and alertness, ***suppressing thyroid and progesterone.*** (Sirotkin, 1997) Women who are depressed have been found to have higher daytime melatonin levels. (Danilenko, et al., 1994) While the popular books have given the impression that there is no question about the protective nature of melatonin, it turns out that **in only five out of 36 strains of inbred mice can melatonin be demonstrated in the pineal glands. The famous cancer prone strain, in which mammary cancer kills practically all the females, is one of these. When they are given melatonin the development of tumors is accelerated. When their pineal gland is removed, their life span is extended.**

Estrogen and stress increase free fatty acids, and unsaturated free fatty acids cause serotonin release; serotonin, at least under some circumstances, can be lipolytic, increasing the free circulating fatty acids.

Darkness creates stress, by free radical inactivation of the respiratory enzyme, cytochrome oxidase, and light restores the activity of that enzyme, and probably also has a variety of anti-free-radical actions. Free fatty acids rise in the darkness, intensifying free radical production and

suppressing respiration. Progesterone synthesis is suppressed by darkness. The serotonin liberated by the fatty acids suppresses progesterone by inhibiting the secretion of luteinizing hormone (LH) which stimulates progesterone synthesis, and also seems to act directly on the ovary to suppress progesterone secretion (Wilson, et al., 1975). While estrogen increases serotonin's actions, progesterone antagonizes them.

Serotonin depletes glycogen stores, much the way estrogen and histamine do. This can cause hyperglycemia. Thyroid, carbon dioxide, and caffeine, which inhibit serotonin release, all tend to protect glycogen stores. Under the influence of carbon dioxide, noradrenaline can still liberate glucose from glycogen, but serotonin's effect is inhibited by carbon dioxide.

Serotonin interferes with slow-wave sleep, creating a situation resembling that of depression or old age. Brain glycogen is depleted in old age, and this depletion contributes to inefficient brain metabolism. Serotonin's stimulation of ACTH, which stimulates the adrenal cortex, and its direct stimulation of cortisone production by the adrenals, is probably involved in the chronic excess of cortisone seen in depression and old age, which contributes to insulin resistance and diabetes, and to the atrophy of all tissues including the brain. (People who are studying chronic inflammatory processes are gathering data that will be meaningful for understanding depression and aging, but it seems that psychiatrists don't know about their work.)

Anti-serotonin drugs such as bromocriptine have been found to correct diabetes, apparently because serotonin interferes with the use of sugar, acting on cells' metabolism to decrease its use, and preventing the secretion of insulin. Bromocriptine's correction of obesity also seems to be the result of its correction of glucose metabolism.

In the 1970s, it was established that darkness increases the appetite for alcohol. More recently (Lin and Hubbard, 1995) it has been found that the antiserotonin drugs prevent the dark-induced appetite for alcohol. Alcohol is probably a self-medication to alleviate serotonin-related depression. Alcohol, like progesterone, is neuroprotective in brain trauma. Alcohol increases formation of the sedative neurosteroid ("THP") derived from progesterone (VanDoren, et al., 2000), and alcohol increases brain circulation, countering serotonin's effect.

Progesterone withdrawal and alcohol withdrawal are so closely related that one can alleviate the symptoms of the other.

Isolation might be another factor contributing to depression and alcoholism, since it decreases the formation of the protective neurosteroid.

The "brain fog" that is often described in depressed people (and people with other serotonin syndromes, such as the fibromyalgia syndrome) is probably produced by a combination of factors, including hypothyroidism, low body temperature, and hyperserotonemia. The amnesia produced by shock was found to be prevented by antiserotonin drugs (Montanaro, et al., 1979). The same researchers suggested that the drugs had an "antipunishment" effect, in effect making the animals less fearful.

There is more confusion in the medical literature regarding the actions of serotonin than there is about practically any other subject.

For example, there is clear evidence from both animal and human studies that serotonin, like estrogen, is associated with aggression, but the dominating stereotype is that serotonin is the agent of serenity and peace. In an epidemiological study (Moffitt, et al., 1998), a record of violence was clearly associated with above-average blood serotonin levels. Animal studies show that darkness stimulates both aggression and eating (Russell and Singer, 1983), and that serotonin increases, while antiserotonin drugs decrease, aggression (Carlini and Lindsey, 1983).

When lysergic acid derivatives came onto the pharmaceutical market, the spirit of the times caused them to be described as dopamine agonists, rather than as serotonin antagonists, but the latter would be at least as descriptive of their effects. Bromocriptine fulfills many of the requirements of being a serotonin antagonist, for example by suppressing prolactin. As a class, the serotonin antagonists have a very interesting place in pharmaceutical medicine, because the broad spectrum of their therapeutic activity suggests the

great variety of problems caused by excess serotonin.

The documentation of extensive government-supported fraud in research on LSD and marihuana should make us question subsequent research that plows the same or similar furrows. My inclination is to believe that incompetence can't account for the glaring errors in research on serotonin-related questions. Commercial commitments to particular theories of drug action have undoubtedly contributed to the crazy quality of the psychiatric serotonin literature.

In the case of some antiserotonin drugs, there is commercial support for research, so they might come into general use in spite of the mythic stature of tryptophan/serotonin/melatonin. But thyroid, protein, magnesium, thiamine, progesterone and light are natural factors that keep serotonin under control, and that don't have the side effects of the synthetic antiserotonergic agents. Knowledge of serotonin's harmful actions can guide our use of the natural protective factors. For example, whey protein contains much more tryptophan than whole milk or cheese does, and would tend to suppress the thyroid and activate the whole serotonin-stress system. Whey might be good food for fattening pigs, but its acceptance in the health food industry as a powdered protein supplement is just another example of the harmful effects of the serotonin mythology.

(Some comments on research methods:)

"Serotonin activity" may be judged by the response of prolactin to serotonin or to a drug that is thought to mimic serotonin, or by serotonin metabolites in cerebrospinal fluid, or by the total amount of serotonin in the blood, or by its efflux from platelets, or the ratio of its concentration in the plasma and in the platelets. It isn't very clear whether serotonin's concentration or its turnover rate is most important, and the number and sensitivity of the many "serotonin receptors" varies, and presumably changes the meaning of any given quantity of serotonin. When serotonin's activity is judged indirectly, interpretation and subjectivity are involved.

Even the "synaptic reuptake inhibitors," such as fluoxetine, sometimes relieve symptoms that are believed to be caused by an excess of serotonin (C. Advokat and V. Kutlesic, 1995, Neurosci Biobehav Rev 1995 Spring;19(1):59-66 Pharmacotherapy of the eating disorders: a commentary.)

But the actual injection of serotonin, or of serotonin antagonists that are known to approximately neutralize serotonin's effects, and the examination of the basal concentrations of the hormones known to be regulated by serotonin, are much less likely to be distorted by arbitrary interpretations.

When a "receptor" is first proposed or "discovered," it is always "a protein," though because of the idea of a barrier (semipermeable) membrane around cells, "membrane lipids" are sometimes invoked. But after a few years of research, the "receptor" becomes a more and more complex system of interacting molecules. The doctrine of the "receptor" is intended to explain why cells have a specific response to a specific substance. Gradually, a receptor becomes a "response element," but the "element," in its complexity, begins to shade off into the system "membrane/cytoplasm/nucleus," which is to say, the cell. ***The cell is the response element.*** *The "transmitter substance" interacts with various agonists, antagonists, inverse agonists and binding competitors to produce an effect that is a summation of influences. A single protein or protein system can serve as a "receptor" for antagonistic substances.*

Int J Circumpolar Health 1998;57 Suppl 1:386-8. **Seasonal variation of the amino acid, L-tryptophan, in interior Alaska.** Levine ME, Duffy LK The seasonal pattern of L-tryptophan was studied in a Fairbanks, Alaska, population that was unadapted to the extreme light variations of the North. Previously, this population was shown to exhibit seasonal behavior effects such as increases in fatigue and sleep duration, as well as endocrine effects such as increases in melatonin levels and phase shifting. Caloric and macronutrient intake have been reported to vary seasonally in humans, thereby potentially

influencing the plasma levels of L-tryptophan, which is a precursor of serotonin and melatonin. Plasma levels of L-tryptophan from volunteers, whose average duration of stay in Alaska was eight months, were determined by automated amino acid analysis. Prominent results included finding increased levels in the winter **at several different diurnal time points. These findings support hypotheses which relate underlying physiological adaptations to the North to the increased incidence of behavioral disorders such as depression and alcoholism.**

Epidemiology 2000 Nov;11(6):660-5. **Alcohol consumption and urinary concentration of 6-sulfatoxymelatonin in healthy women.** Stevens RG, Davis S, Mirick DK, Kheifets L, Kaune W **"We found that the nocturnal urinary concentration of the primary metabolite of melatonin (6-sulfatoxymelatonin) decreased in a dose-dependent manner with increasing consumption of alcoholic beverages in the preceding 24-hour period, after taking into account the independent effects on melatonin of age, hours of darkness, use of medications that affect melatonin levels, and body mass index. A categorical analysis revealed no effect of one drink, but a 9% reduction with two drinks, a 15% reduction with three drinks, and a 17% reduction with four or more drinks."**

Fertil Steril 1993 Apr;59(4):896-900. **Baboon corpus luteum: the effect of melatonin on in vitro progesterone production.** Khan-Dawood FS, Dawood MY **"Melatonin (0.01 to 1.0 ng/mL) inhibited basal P production in all the CL (41.8 +/- 9.9 ng P without melatonin compared with 32.2 +/- 2.0 ng P, 28.4 +/- 2.1 ng with 0.01 and 1.0 ng/mL melatonin, respectively). Human chorionic gonadotropin-stimulated P production was significantly inhibited with as little as 0.01 ng of melatonin** (150.8 +/- 11.4 ng with 10 IU hCG versus 120.3 +/- 6.4 ng with 10 IU hCG and 1.0 ng melatonin). The degree of inhibition in the hCG-stimulated cells was greater than in the nonstimulated cells. Melatonin at a concentration of 0.001 ng/mL did not affect P production in both stimulated and nonstimulated cells. Serotonin in similar concentrations had no effect on luteal cell P production." "These findings indicate that melatonin exerts a suppressive effect on baboon dispersed luteal cell P production and thus may play a role in luteal function."

Physiol Behav 1983 Jan;30(1):23-7. **Relations between muricide, circadian rhythm and consummatory behavior.** Russell JW, Singer G Three forms of behavior--muricide, eating, and drinking--have been studied at six photic periods during a 12/12 hr light/dark circadian cycle to which the subjects have been habituated. One hundred and eight rats served as subjects, 18 per photic period. The frequency of muricide was recorded for each period and subsequent food and water intakes were measured during a 1 hr test period. **Results show a significantly higher frequency of muricide during the dark than during periods of light.** Food intake covaried significantly with the incidence of muricide rs = 0.89, p less than 0.05), while no such relationship was found between muricide and water intake (rs = 0.17, p less than 0.05). **The findings are consistent with reports of circadian changes in other rodent behaviors, including rhythmicity in home-cage and in shock-induced aggression.** Covariation of muricide and eating does not establish a causal relation between the two. Three models of physiological mechanisms which might provide substrates for the covariance are discussed.

Semin Clin Neuropsychiatry 2000 Apr;5(2):125-31. **Serotonin and amino acids: partners in delirium pathophysiology?** van der Mast RC, Fekkes D "Serotonin is one of the neurotransmitters that may play an important role in medical and surgical delirium. Normal serotonin synthesis and release in the human brain is, among others, dependent on the availability of its precursor tryptophan (Trp) from blood. **The essential amino acid Trp competes with the other large neutral amino acids (LNAA) tyrosine, phenylalanine, valine, leucine, and isoleucine for transport** across the blood-brain barrier. This competition determines its uptake into the brain, represented by the ratio of the plasma level of Trp to the sum of the other LNAA. The plasma ratio of Trp/LNAA, plasma level of Trp, and serotonin in plasma and platelets have been used as indirect peripheral measures for central serotonergic functioning. Both increased and decreased serotonergic activity have been associated with delirium. **Serotonin agonists can induce psychosis, both elevated Trp availability and increased cerebral serotonin have been associated with hepatic encephalopathy, and excess serotonergic brain activity has been related to the development of the serotonin syndrome of which delirium is a main symptom.** On the other hand, alcohol withdrawal delirium, delirium in levodopa-treated Parkinson patients, and postoperative delirium have been related to reduce cerebral Trp availability from plasma suggesting diminished serotonergic function. Rick factors for delirium such as severe illness, surgery, and trauma can induce immune activation and a physical stress response comprising increased activity of the limbic-hypothalamic-pituitary-adrenocortical axis, the occurrence of a low T3 syndrome, and, possibly, changes in

the permeability of the blood-brain barrier. There are indications that these changes have their effect on plasma amino acid concentrations, e.g., Trp, and multiple cerebral neurotransmitters, including serotonin. This stress response may be different depending on the stage of illness being acute or chronic."

J Neurosci 2000 Mar 1;20(5):1982-9. **Neuroactive steroid 3alpha-hydroxy-5alpha-pregnan-20-one modulates electrophysiological and behavioral actions of ethanol.** VanDoren MJ, Matthews DB, Janis GC, Grobin AC, Devaud LL, Morrow AL Neuroactive steroids are synthesized de novo in brain, yet their physiological significance remains elusive. We provide biochemical, electrophysiological, and behavioral evidence that several specific actions of alcohol (ethanol) are mediated by the neurosteroid 3alpha-hydroxy-5alpha-pregnan-20-one (3alpha,5alpha-THP; allopregnanolone). **Systemic alcohol administration elevates 3alpha, 5alpha-THP levels in the cerebral cortex to pharmacologically relevant concentrations.** The elevation of 3alpha,5alpha-THP is dose- and time-dependent. Furthermore, there is a significant correlation between 3alpha,5alpha-THP levels in cerebral cortex and the hypnotic effect of ethanol. **Blockade of de novo biosynthesis of 5alpha-reduced steroids using the 5alpha-reductase inhibitor finasteride prevents several effects of ethanol.** Pretreatment with finasteride causes no changes in baseline bicuculline-induced seizure threshold but reverses the anticonvulsant effect of ethanol. Finasteride pretreatment also reverses ethanol inhibition of spontaneous neural activity in medial septal/diagonal band of Broca neurons while having no direct effect on spontaneous firing rates. Thus, elevation of 3alpha,5alpha-THP levels by acute ethanol administration represents a novel mechanism of ethanol action as well as an important modulatory role for neurosteroids in the CNS.

Braz J Med Biol Res 1982 Oct;15(4-5):281-3. **Effect of serotonergic drugs on the aggressiveness induced by delta 9-tetrahydrocannabinol in rem-sleep-deprived rats.** Carlini EA, Lindsey CJ **1. delta 9-Tetrahydrocannabinol (THC) induced aggressive behavior in rats previously deprived of REM sleep. This aggressiveness was significantly potentiated by tryptophan and fluoxetine, drugs which increase brain serotonin** availability. 2. Conversely, **drugs which decrease serotonergic function such as D,L-p-chlorophenylalanine, cinanserin and cyproheptadine strongly blocked the aggressive behavior**. 3. On the basis of previous data indicating an involvement of dopaminergic mechanisms in this type of aggressiveness and the present results showing a role for serotonin, it is concluded that REM deprivation-THC aggression is under the control of at least these two neurotransmitters.

Endocrinol Exp 1979 Mar;13(1):9-18. **Inhibitory role of brain stem serotoninergic neuron system on thyroid function in rat.** Ruzsas C, Jozsa R, Mess B Thyroid function was investigated in adult male rats following the use experimental procedures which inhibit the activity of serotoninergic neuron system. Pharmacological blockade of the biosynthesis of sertonin by repeated administration of para-chlorophenylalanine (pCPA), or interruption (by Halasz knife) of the serotoninergic pathways of the brain stem which terminate on hypothalamic nuclei equally resulted in an augmentation of the following **parameters of hypothalamo-hypophysial-thyroid activity: T/S ratio, pituitary and blood TSH levels and blood thyroxine concentration as well as TRH content of the hypothalamus. The results suggest that the central nervous serotoninergic neuron system plays an inhibitory role in the regulation of TSH secretion, presumably** acting upon the hypothalamus, thereby inhibiting hypothalamic TRH secretion.

Vopr Onkol 2000;46(3):311-9. **[The effect of melatonin on the indices of biological age, on longevity and on the development of spontaneous tumors in mice].** Anisimov VN, Zavarzina NI, Zabezhinskii MA, Popovich IG, Anikin IV, Zimina OA, Solov'ev MV, Shtylik AV, Arutiunian AV, Oparina TI, Prokopenko VM, Khavinson VK Fifty female CBA mice were given melatonin with drinking water (20 mg/l) for 5 consecutive days monthly, beginning from the age of 6 months, until natural death. Another 50 intact mice were used as controls. Melatonin failed to significantly influence body weight or food consumption. **Age-related switching-off of estrus function was delayed, body temperature decreased. Somewhat decreased motor activity did not affect physical one or endurance. Increase in life span led to higher spontaneous tumor incidence.** Another experiment using 20 animals of the same line showed melatonin to inhibit free-radical processes. A conclusion was drawn that caution should be exercised before melatonin is recommended for long-term administration as a geroprotector.

Am J Psychiatry 1983 Jan;140(1):26-30. **Hyperserotonemia and platelet serotonin uptake and release in schizophrenia and affective disorders.** Stahl SM, Woo DJ, Mefford IN, Berger PA, Ciaranello RD **The authors found that platelet serotonin concentrations were significantly elevated in patients with chronic schizophrenia and in patients with bipolar major depressive disorder. High-affinity serotonin uptake was significantly reduced only in patients with bipolar major depressive disorder.** Thrombin-induced release of serotonin from platelets in any patient group was not

different from that of normal control subjects. Platelet serotonin storage in chronic schizophrenic patients was also not different from that in normal control subjects. These platelet findings could not be explained by age, sex, or medication variables. The authors suggest that the pharmacodynamics of platelet serotonin may be different in chronic schizophrenia than in bipolar major depressive disorder.

Arctic Med Res 1994 Jul;53(3):137-45 **Diurnal and seasonal variations of melatonin and serotonin in women with seasonal affective disorder.** Danilenko KV, Putilov AA, Russkikh GS, Duffy LK, Ebbesson SO In winters 1990-1991 and 1991-1992 women with and without seasonal affective disorder, winter type, were treated by light at 2500 lux either in the morning (0800h-1000h) or afternoon (1600h-1800h). In winter before light treatment, **melatonin levels in serum in daytime (1200h and 1600h) were higher in patients compared to controls ($p < 0.05$). This difference disappeared in the summer or** after light treatment in the winter. Also, light treatment and change in season resulted in a phase advance shift of melatonin rhythm in patients. The decline in melatonin levels correlated with the decline in specific SAD symptoms of hyperphagia and carbohydrate craving. In winter, neither patients nor controls showed significant diurnal variations in levels of whole blood serotonin. In both patients and controls, levels of serotonin were higher in summer as compared with winter, especially at 2000h. Our data suggest that elevated daytime melatonin can be a state marker of winter depression, and that seasonal change of photoperiod may also affect the circadian amplitude and daytime levels of blood serotonin.

Lik Sprava 1994 Jul-Aug;(7-8):88-90. **[The effect of an increased intensity of light on changes in the serotonin and melatonin content in patients with depression].** [Article in Russian] Bozhko GK, Tsaritsinskii VI, Kostiukovskaia LS, Kulabukhov VM Study into the effect of **light of increased intensity shows that in patients with anxious depression a high level of melatonin excretion declines to normal,** its low level in melancholic depression remaining unchanged. Blood **concentrations of serotonin in depressive patients are higher as compared with the healthy persons** and do not change with increasing in the brightness of the illumination **except for a decrease in a portion of patients showing maximum levels of serotonin and melanin.**

Brain Res Bull 1994;33(6):633-8. **The increased ethanol preference in rats induced by choice, darkness, or drugs is reduced by ritanserin.** Lin N, Hubbard JI We tested the hypothesis that ritanserin, a serotonin S2 antagonist, reduces voluntary and induced forms of ethanol drinking. We gave 10 mg/kg ritanserin IP or SC to groups of rats given either a) a free choice between 3% ethanol and water, or b) kept in the dark for 5 weeks and given a choice between a range of ethanol concentrations (3-25%) and water, or c) implanted with osmotic pumps filled with tetrahydro-beta carboline and given a choice between a range of ethanol concentrations and water. In each case, ritanserin significantly reduced ethanol consumption and ethanol preference for 8-10 days after the last injection.

Neuropsychobiology 1979;5(3):174-80. **Bromolysergide and methysergide protection against ECS-induced retrograde amnesia.** Montanaro N, Dall'Olio R, Gandolfi O Bromolysergide (BOL 148) and methysergide (UML 491), 2 mg/kg intraperitoneally, and saline were administered to rats 45 min before one-trial passive-avoidance conditioning followed by electroconvulsive shock (ECS) or sham-ECS (ECS). On test session (24 h later), the groups treated with both BOL 148 and UML 491 exhibited a clear-cut retention in comparison to saline-ECS rats. On the other hand, all drugged groups, regardless of their submission to ECS, showed a little less pronounced consolidation than saline-ECS rats. The antiamnestic effect **brought about by the two drugs was discussed in terms of receptor antagonism against ECS-released brain serotonin, whereas the lower passive-avoidance level** observed in treated animals was considered in relation to a possible **antipunishment effect of antiserotoninergic treatment.**

J Neural Transm 1981;50(1):1-12. **Depletion in amygdaloid 5-hydroxytryptamine concentration and changes in social and aggressive behaviour.** File SE, James TA, MacLeod NK 5,7-Dihydroxytryptamine (10 and 20 microgram) was microinjected bilaterally into **the amygdaloid complex of rats and resulted in 55% and 80% depletion in 5-hydroxytryptamine concentration, respectively. The lesioned animals exhibited fewer dominance behaviours and submitted more often to an intruder into their home-cages than did the vehicle-injected controls. The lesioned rats were also more submissive than were the controls when they were intruding into another** rat's territory. Only the higher dose of toxin altered social investigatory behaviour when this was measured in an arena in which neither rat had established territory. The lesioned rats displayed less social interaction and had reduced levels of motor activity. The results are compared with those of other studies in which there

has been regional or general depletion of brain 5-hydroxytryptamine concentration.

J Neuroimmunol 2000 Aug 1;108(1-2):131-5. **The pineal gland and cancer. I. Pinealectomy corrects congenital hormonal dysfunctions and prolongs life of cancer-prone C3H/He mice.** Bulian D, Pierpaoli W. **Hormonal derangements almost invariably anticipate and signal the onset of tumors.** Chronic, nocturnal melatonin administration delays aging in normal strains of mice. **On the contrary it promotes and accelerates the onset of tumors in the cancer-prone strain of C3H/He mice.** Grafting of a young pineal gland into aging mice prolongs their longevity and maintains juvenile circadian hormonal functions while pinealectomy (Px) does the opposite. We investigated if Px in C3H/He mice would modify their congenitally deranged pituitary function and affect their longevity. It was found that contrarily to Px in normal mice, Px in **C3H/He mice remarkably maintains juvenile night levels of thyroid hormones and lipids, preserves a cell-mediated immune response and significantly prolongs their life. The pineal gland and its pathology may be the key for understanding,** not only the causes of metabolic aging, but also the origin of those congenital or progressive aging-related hormonal alterations preceding onset of all tumors and thus allow preventive corrective interventions with pineal-derived agents.

J Pineal Res 1989;7(2):195-204. **Melatonin content of the pineal gland in different mouse strains.** Goto M, Oshima I, Tomita T, Ebihara S. Pineal melatonin content at several times during the day and night was measured in 36 inbred strains of mice (Mus musculus) kept under LD 12:12 cycles. The **results have indicated that only five inbred strains have pineal melatonin content, with higher levels during the night and lower levels during the day; the other 31 strains do not contain detectable melatonin in their pineal gland at any of times examined.** The former group includes two commonly used strains (C3H/He and CBA/Ms) and three wild-derived strains (Mol-A, Mol-Nis, MOM). C3H and CBA mice showed a similar pattern of pineal melatonin rhythm with a peak at 2 hours before lights on. The peak levels were about 150 pg/gland in both strains. The rhythmic patterns of melatonin content in Mol-A, Mol-Nis, and MOM were slightly different from those in CBA and C3H. In the wild-derived strains, the peak of melatonin content did not occur at 2 hours before lights on but tended to occur at midnight. The peak levels were 67-91 pg/gland at the highest point in these strains.

Am J Obstet Gynecol 1985 Sep 15;153(2):130-4. **The effect of serotonergic blockade in postpartum preeclamptic patients.** Montenegro R, Knuppel RA, Shah D, O'Brien WF Thirty postpartum preeclamptic patients from the University of South Florida Obstetrical Service were enrolled in a placebo-controlled, randomized, double-blind study to test the effectiveness of ketanserin in lowering the blood pressure. **An intravenous bolus of ketanserin resulted in a significant drop in the mean arterial blood pressure. The decrease in the blood pressure could be maintained by a continuous infusion of ketanserin.** Hypertension returned after the medication was discontinued. These observations suggest that ketanserin, a selective blocker of type II serotonin receptors, may be effective in **acutely reducing elevated postpartum blood pressure in preeclamptic patients,** and that serotonin may play a role in the pathogenesis of preeclampsia, but not be important as a mediator in the severity of the disease.

Eur J Pharmacol 1985 May 8;111(2):211-20. **Maternal aggression in mice: effects of treatments with PCPA, 5-HTP and 5-HT receptor antagonists.** Ieni JR, Thurmond JB Drug treatments which influence brain serotonergic systems were administered to lactating female mice during the early postpartum period, and their effects on aggressive behavior, locomotor activity and brain monoamines were examined. P-chlorophenylalanine (200 and 400 mg/kg) and 5-hydroxytryptophan (100 mg/kg) inhibited fighting behavior of postpartum mice toward unfamiliar male intruder mice. These drug-treated postpartum females showed increased latencies to attack male intruders and also reduced frequencies of attack. In addition, postpartum **mice treated with the serotonin receptor antagonists, mianserin (2 and 4 mg/kg), methysergide (4 mg/kg) and methiothepin (0.25 and 0.5 mg/kg), displayed significantly less aggressive behavior than control mice, as measured by reduced** number of attacks. Whole brain monoamine and monoamine metabolite levels were measured after drug treatments. The behavioral results are discussed in terms of drug-induced changes in brain chemistry and indicate a possible role for serotonin in the mediation of maternal aggressive behavior of mice.

Lungs, shock, inflammation, and aging

There is a growing effort by the food and drug industries, and many physicians, to promote the use of certain polyunsaturated fatty acids, those with their double bonds farthest from the acidic end of the molecule. These fats, which are found in fish, algae, and many vegetables, are the most easily oxidized of the common fatty acids. With stress, such as premature birth, and with aging, these fats produce free radical decomposition products at a high rate. They contribute to "shock lung" and to multiple organ failure.

After I had done my dissertation on the changes in oxygen metabolism that occur during aging and under the influence of estrogen, and not long after I had seen the therapeutic effects of progesterone in epilepsy, arthritis, depression, and multiple sclerosis, I met a woman who was disabled with some kind of inflammatory muscle and joint disease. Her face, arms, and upper torso were emaciated, but her hips and thighs were huge. This pattern of fat distribution is typical of the extreme and prolonged influence of estrogen.

In discussing her health history, she said that her movement problems began at the age of 21, when her physician-father began giving both her and her mother regular injections of estrogen.

Having a doctor in the family, they had the most complex medical studies done in trying to diagnose their problems. The thing that stood out in her description of the tests was the pulmonary oxygen diffusion test, which she said showed that both she and her mother had oxygen diffusing capacity that were "95% below normal." I think she might have meant that they were in the lowest 5 percent of the population, since I can't think of another interpretation that would be compatible with life. Right around that time, I read a study in which mice were given a large dose of estrogen, which, after just 40 minutes, caused a similarly radical decrease in their oxygen diffusing capacity.

In the late 1960s, I had been interested in the use by athletes of a drink made by foaming oxygen into a solution of gelatin, to increase their blood oxygenation and their performance. I tried to talk to a few physician-researchers about this, and they firmly said that it was nonsensical, because "blood is always fully oxygenated when it leaves the lungs." Looking in the science library at the university, I found a recent (c. 1968) study in which the blood's oxygenation was found to decline with aging, commonly down to about 50%. But despite the mouse study, I didn't find any studies regarding estrogen's effects on oxygen diffusion in humans. I believed that the reason was the same as the denial that athlete's blood might not be fully oxygenated, namely, a stupefying degree of authoritarianism and a need to absolutize anything that was in a medical textbook.

About 15 years later, I visited a friend who was 82 years old, who lived in Toluca, Mexico. When I first saw him, I could see that he didn't recognize me. He was sitting down, breathing heavily, and his face was purplish. He had been diagnosed as having emphysema, and hadn't been able to work for several weeks. Since he was very fat, I guessed that he might be suffering from the

". . . at a maximum level of exertion, the heart at high altitude is relying less on glycolysis (anaerobic energy production), and getting more of its energy from oxygen, than it would at sea level." This means that sea-level metabolism is more like cancer metabolism, because of the high oxygen/carbon dioxide ratio.

same sort of estrogen-provoked diffusion problem that I had run across previously. I left his daughter some progesterone and pregnenolone to give him, and left Toluca for several days. The next time I saw him, his skin had a better color, and his humor had returned. When I came back again two weeks after he had started taking progesterone and pregnenolone, his color was entirely normal, he had resumed working in his office (in a building that didn't have an elevator), and he insisted on taking me around the city, causing me to pant because of the altitude, about 8,500 feet above sea level.

In the 1950s, Gilbert Ling found that, under the influence of increased carbon dioxide, excitable cells don't "depolarize" electrically[1] to the extent that they do under a normal atmosphere. This principle has been applied to treat epilepsy, by breathing air with a few percent of carbon dioxide added, and more often, the principle has been used in the "diagnosis" of epilepsy, by using hyperventilation to induce seizures, by displacing too much carbon dioxide. Carbon dioxide spontaneously forms carbamino groups by reacting with the amino groups in proteins, and increasing the oxygen pressure causes the carbon dioxide to be displaced.

The binding of the acidic carbon dioxide to the protein molecule shifts electrons in the protein, making it more acidic. This shift in the protein changes the way the protein interacts with other molecules, including water, sodium, potassium, and calcium. Under the relatively acidic conditions when carbon dioxide is abundant, with the cell proteins' average electrons slightly "retracted," free radical production is inhibited, and cells are more resistant to radiation damage or other excitatory damage.

Carbon dioxide, along with the carbonic acid it forms as it reacts with water, regulates the organism's handling of water.

Carbon dioxide's association with cells has many effects, including the regulation of hormones and nerve transmitters. For example, carbon dioxide causes cells to bind serotonin, so that a loss of carbon dioxide causes serotonin to be released, with the effect that blood vessels become more permeable, and leak fluid (including serum proteins) into the surrounding spaces.

In the lungs, this leakage of fluid is very inconvenient.

In any tissue, the leakage of serum creates an additional barrier to the diffusion of oxygen from the blood to the tissue cells. The hypoxic cells release lactic acid and other mediators of inflammation, and the walls of the capillaries and other blood vessels thicken, making the proper circulation of the blood more difficult. These effects are usually overlooked in the brain and the heart, but in the lung they are hard to miss. Following a stressful death, the lungs are waterlogged, with a great increase in weight, a condition called "shock lung" or "wet lung."

The antiexcitatory action of carbon dioxide is opposed by oxygen, so oxygen can, in this context, be considered as a cell excitatory agent. At increased pressure, pure oxygen causes seizures, and even at normal pressure, the lungs are more likely to be damaged when there is more oxygen. Since the lungs' delicate membranes are in direct contact with air, it's obvious that they are in a vulnerable situation, easily losing too much carbon dioxide in the presence of excessive oxygen.

At high altitudes, once a person has adapted to the lower oxygen pressure, the tissues retain more carbon dioxide, and this prevents cells from being activated to the same extent that's possible at low altitude, so there is less lactic acid produced. The carbon dioxide makes the blood circulate more easily, so the heart works less to circulate the blood at the same rate that it would circulate at sea level, or even at a higher rate, and even **at a maximum level of exertion, it is relying less on glycolysis (anaerobic energy production), and getting more of its energy from oxygen, than it would at sea level.**

[1] In the normal resting state, a cell is "polarized." In the depolarized state, a cell is vulnerable, and if it is too frequently depolarized, it can be damaged or killed in the process called "excitotoxicity," and other related degenerative processes. Cancer cells are chronically "depolarized," and this is related to their low-efficiency metabolism.

Some people, who have a respiratory problem at sea level, react to high altitude by breathing so hard that they lose even more carbon dioxide than they were losing at low altitude, and they may develop lung edema, and even brain edema and seizures. With lung edema, breathing becomes harder, and the heart works harder. It has been discovered repeatedly over the years that altitude sickness can be treated successfully with supplemental carbon dioxide. The now-standard treatment for mountain sickness is the drug acetazolamide, which causes the body to retain carbon dioxide. Despite the drug's success in preventing and curing altitude sickness, there is a weird reluctance to acknowledge that mountain sickness is produced by an insufficiency of carbon dioxide. The same drug is now often used to treat sleep apnea, despite the textbooks' opinion that sleep apnea is caused by too much carbon dioxide, rather than by the alkalosis resulting from insufficient carbon dioxide.

If we think of the presence of lactic acid as evidence of metabolic inefficiency, then an athlete, or anyone who exercises strenuously, has a low degree of efficiency, especially at sea level. Despite the presence of oxygen that isn't being consumed at a maximum rate, glycolysis becomes very intense, producing lactic acid that apparently helps to limit the full use of the available oxygen. It is probably the high oxygen pressure, wasting carbon dioxide, that turns on the lower efficiency lactic acid-producing glycolysis.

"Hypoxemia of exercise," the failure of the blood to be fully oxygenated during strenuous activity, is very similar to the chronic hypoxemia that occurs in the "respiratory distress syndrome." Women ahtletes have a greater tendency to exercise hypoxemia then men. In the luteal phase, when progesterone should be dominant, women breathe more effectively than during the estrogen-dominated follicular phase of the cycle. Since estrogen, like exercise, causes blood vessels to leak fluid, this isn't surprising. Stress, such as exercise or sickness, causes a significant rise of estrogen, along with the other mediators of inflammation, even in men.

Both exercise and estrogen dominance cause fatty acids to be liberated from the tissues. The unsaturated fatty acids increase the permeability of capillaries, and the ratio of unsaturated fatty acids to saturated fatty acids corresponds closely to the degree of lung malfunction and respiratory distress. (Baughman, et al., 1984) The medium chain saturated triglycerides, extracted from coconut oil, can be used for intravenous feeding without causing the respiratory distress and lung damage produced by the unsaturated vegetable oils that were formerly used.

The long chain polyunsaturated fatty acids, including linoleic, linolenic, arachidonic, and docosahexaenoic (DHA) acids, cause mitochondrial breakdown, thyroid suppression, vascular permeability, brain edema, and increased radiation sensitivity.

DHA is the most unstable of these unsaturated fatty acids. But there is at present a very poweful marketing campaign which argues that DHA should be added to baby formula and should be taken by adults, because we supposedly "evolved on a diet rich in n-3 fatty acids," and because our tissues generally contain a much lower concentration of the n-3 fats than of the n-6 fats.

There is evidence that the low ratio of these n-3 fatty acids, such as DHA (docosohexaenoic acid), to the n-6 fats, such as arachidonic acid, is the result of the fact that the n-3 fats are extremely unstable, and break down rapidly in the tissues, producing lipid peroxides, free radicals, and the characteristic ethane, which can be measured in the breath. Stress accelerates the decomposition of these fats, and the resulting ethane can be detected in higher amounts during respiratory distress, and in premature babies and in older people.

Mead Johnson has announced that it will add DHA to their baby formula, arguing that it is an essential nutrient for eye and brain development. But animals that are fed a diet that is "deficient in" DHA are less susceptible to eye damage than animals that have "sufficient" DHA. But more generally, animals that are deficient in ***all of the so-called "essential fatty acids"*** are extremely resistant to all sorts of injury, shock, and poisoning.

Since all of the polyunsaturated fats inhibit thyroid function, and since the thyroid hormone is essential for the development of the brain and

lungs, increased use of polyunsaturated oils will increase the incidence of hypothyroidism, leading to the birth of more premature babies with lung disease. With a high concentration of polyunsaturated fats in the lungs, the exposure of the newborn's lungs to oxygen will create an inflammatory reaction. This is probably why the respiratory distress of prematurity usually takes a few days to appear. Considering what is known about oxygen, lungs, and DHA, I think it would be reasonable to say that increased use of DHA would be the ideal way to increase infant lung disease.

The unsaturated fats and estrogen contribute to the increased release of serotonin and nitric oxide (NO). Nitric oxide is produced during inflammation, and, like ethane, can be detected in the breath when the lungs are inflamed. Nitric oxide, as a pro-inflammatory free radical, stimulates the peroxidation of the unsaturated fats. Both NO and serotonin inhibit mitochondrial respiration, shifting metabolism toward glycolysis.

Since the processes that damage the lungs are so similar in aging, stress, and prematurity, I think an examination of the factors that cause premature birth will be useful for understanding the general problem of "lung stress."

Preeclampsia, or a syndrome of pregnancy induced hypertension, occurs in about 10% of pregnancies, and it's the main cause of maternal death and sickness of the newborn.

Thomas Brewer, about 50 years ago, made it clear that a protein deficiency is the main cause of preeclampsia. Protein deficiency causes a general inflammatory condition, with increased serotonin.

In women with preeclampsia, there are abnormally high levels of serotonin, nitric oxide, and lipid peroxidation.

In a study of more than 3000 women (Clausen, et al., 2001), the consumption of sugar and polyunsaturated fat was strongly associated with the development of preeclampsia. Women who don't eat enough protein are likely to substitute sugar and fat for the absent protein, so this study is consistent with Brewer's work, but it's very important to see that it was polyunsaturated fats, not saturated or monounsaturated fats, that caused the problem. Eclampsia (pregnancy- related seizures) and preeclampsia are caused by oxidative stress, produced by the excessive unstable fats. The increased serotonin and nitric oxide are exactly what would be expected to result from the high consumption of polyunsaturated fats, especially with a deficiency of protein in the diet.

Protein deficiency, like an excess of polyunsaturated fats, causes a thyroid deficiency. Supplements of thyroid, given during gestation, accelerate the maturation of the baby's lungs, and prevent the respiratory distress syndrome.

The use of adequate protein and saturated fats during pregnancy will prevent many of the problems of pregnancy and infancy, but since the unsaturated fats remain stored in the tissues for many years, and are mobilized during stress, it's important to eat correctly long before pregnancy. The requirement for vitamin E remains high for years after the diet has contained an excess of the polyunsatured fats.

The diet which protects the developing fetus happens to be the diet that protects adults from all sorts of stress, and prevents many of the worst symptoms of aging.

Supplemental thyroid, pregnenolone, and progesterone can partly make up for defects in the diet, by maintaining a better balance between carbon dioxide and lactic acid, and by restraining the various mediators of stress, such as NO, serotonin, and estrogen.

The purpose of this study was to investigate in healthy humans the effect of eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) intake, alone or in combination with dL-alpha-tocopherol acetate (vitamin E) supplements on lipid peroxidation. Eighty men were randomly assigned in a double-blind fashion to take daily for 6 wk either menhaden oil (6.26 g, n-3 fatty acids) or olive oil supplements with either vitamin E (900 IU) or its placebo. Antioxidant vitamins, phospholipid composition, malondialdehyde (MDA), and lipid peroxides were measured in the plasma at baseline and week 6. At the same time, breath alkane output was measured. Plasma alpha-tocopherol concentration increased in those receiving vitamin E ($P < 0.0001$). In those supplemented with n-3 fatty acids, **EPA and DHA increased in plasma phospholipids ($P < 0.0001$) and**

plasma MDA and lipid peroxides increased ($P < 0.001$ and $P < 0.05$, respectively). Breath alkane output did not change significantly and vitamin E intake did not prevent the **increase in lipid peroxidation during menhaden oil supplementation. The results** demonstrate that supplementing the diet with n-3 fatty acids resulted in an increase in lipid peroxidation, as measured by plasma MDA release and lipid peroxide products, which was not suppressed by vitamin E supplementation.

OBJECTIVE: Preeclampsia is associated with high body mass index, insulin resistance, and hypertriglyceridemia. Our objective was to investigate prospectively whether diet in the first half of pregnancy is associated with the risk for preeclampsia. STUDY DESIGN: This prospective, population-based, cohort study of pregnant women investigated dietary intake early in the second trimester with a quantitative food frequency questionnaire. RESULTS: The questionnaire was completed by **3133 women** (83%). Preeclampsia developed in 85 women. Adjusted odds ratio (95% CI) for preeclampsia was 3.7 (1.5-8.9) for energy intake of >3350 kcal/d compared with < or =2000 kcal/d. Adjusted odds ratio (95% CI) for preeclampsia was 3.6 (1.3-9.8) for sucrose intake (percent of total energy) of >25% compared with < or =8.5% and 2.6 (1.3-5.4) for polyunsaturated fatty acids intake (percent of total energy) of >7.5% compared with < or =5.2%. Other energy-providing nutrients were not associated with the risk for preeclampsia. CONCLUSION: The current study suggests that high intakes of energy, sucrose, and polyunsaturated fatty acids independently increase the risk for preeclampsia.

Thirty patients (17 with restrictive, eight with chronic obstructive pulmonary disease and five with combined pulmonary changes) were studied. Ordinary pulmonary function tests were made and in addition the transfer factor (diffusion capacity) was measured at rest and compared to the arterial oxygen tension at rest and during maximal exercise. There

was a significant correlation (r = 0.89) **between the transfer factor at rest and the oxygen tension during maximal exercise in both the patients with restrictive and those with obstructive lung disease, but no correlation was found between the transfer factor and the resting oxygen tension. Exercise induced hypoxaemia (PO2 less than 8-8.5 kPa) occurred in some patients and this could be predicted with an excellent sensitivity and specificity if a discrimination point for the transfer** factor of 50 per cent of predicted or less was chosen. Determination of the transfer factor at rest is thus a good screening test for exertional hypoxaemia and can be used to select patients for exercise testing when the purpose is to detect hypoxaemia.

Industrial Toxicology and Occupational Medicine Unit, School of Medicine, Catholic University of Louvain, Brussels, Belgium. The oxygen dependence of ethane formation was investigated in rat lung and liver homogenates, incubated in sealed flasks, in which the peroxidation was stimulated by the addition of ferrous ions. For both tissues, the production of ethane was maximal under a 20% oxygenated gas phase, while hyperoxic conditions led to a decreased ethane in the gas phase. The formation of thiobarbituric **acid-reactive substances (TBA-RS), another marker of the lipid peroxidation process, in the homogenates of lung and liver was strongly stimulated at 100% compared to 20% oxygen. Experiments were also carried out on iron-stimulated peroxidation of pure docosahexaenoic acid preparations, which under air led to a large production of ethane.** As for tissue homogenates, the TBA-RS content was increased in the presence of 100% oxygen. Those conditions, however, did not induce an increase in ethane production but led to the formation of ethanol. **Therefore, the quenching of ethyl radical by molecular oxygen seems to be a very attractive hypothesis to explain the lack of increased ethane production in favor of ethanol when iron-induced lipid peroxidation was stimulated by oxygen.**

Ned Tijdschr Geneeskd 2001 Dec 29;145(52):2521-5. **[Administration of glucocorticosteroids to premature infants: increasing evidence of adverse effects]** van Bel F. **Neonatal glucocorticosteroid therapy is increasingly being used for the prevention of chronic lung disease in very premature infants. In the short term this therapy is usually successful. There is, however, increasing evidence for long-term adverse effects. In particular there seems to be an increased chance of abnormal brain development, which later results in locomotory dysfunction,** developmental delay and cerebral palsy. From experimental studies there are indications that cardiovascular and immunological complications may occur during adult life. Long-term follow-up of neonates treated with glucocorticosteroids seems warranted so that adverse effects that may occur later can be detected and where possible treated. Moreover, the development of alternative treatments should be considered such as the use of less potent glucocorticosteroids.

Thought and energy, mood and metabolism

"Thought doesn't take any energy, thinking doesn't increase the brain's metabolic rate." For several decades, that was the received opinion of the professionals in psychology and neurology. An experiment was cited. But anyone who knew how to think knew otherwise: Hard thought would increase your temperature, prolonged hard thought would make you hungry, and if you didn't eat, prolonged hard thought could make you sick.

The energetic physiology of nerves and muscles had been studied and it was clear that a stimulated nerve expended energy and consumed energy at a higher rate than a resting nerve. The people who chose to believe the silly doctrine about brain metabolism had to believe that the activity of the nerves in the brain was no more intense during intense thought than at rest. It was something that should have been impossible to believe, sort of like the magic bullet theory of the Warren Commission, in which the bullet that killed the president later injured the governor in several places, leaving several metal fragments in his body, and then was found undamaged on a stretcher. With a strong reason to believe, anything can be believed, and the consequences of holding that belief can be great, seeming to validate the reason for choosing to believe.

Energy, thought, and language flow in one direction, through time, building up persistent structures. The structure of a flame, or of a sentence, is definite, but it takes its form from its situation. The symbolic aspect of language is trivial, subordinate to the energy that supports it.

God guard me from those thoughts men think
In the mind alone.
He that sings a lasting song
Thinks in a marrow-bone.
W. B. Yeats' "Prayer for old age":

In the nineteenth century, Sechenov had explained the brain's activity in terms of nervous reflexes. Vvedensky, Pavlov, and Anokhin had refined the implications of that view. But another school condemned the reflex theory of mental activity as crude materialism, and argued, like Descartes, that the brain's activity was immaterial, spiritual, and symbolic.

John Eccles, who was the most prestigious neurologist in England and America, argued that consciousness was completely immaterial. He took Heisenberg's "uncertainty principle" as a way to argue* that physical laws didn't really control the brain, that the whole system hinged on indeterminacy, and that the randomness of that hypothetical microscopic level provided a foothold for the immaterial soul in the brain. Noam Chomsky went directly from Descartes' view of the immaterial consciousness to human grammar, arguing that it was not necessary to investigate the brain at all, to be able to understand how we can produce and understand language. If a set of rules could "account for" or, in mathematical language, "generate," the grammatical structure of language, the rules would adequately describe the "genetic endowment" (itself a set of rules) that made language possible. The brain itself was to be treated as a "black box," whose function was to be inferred by

**Building any sort of superstructure upon the uncertainty principle is to get something from nothing. The uncertainty principle is a basis for nescience, not for knowledge.*

analysis of language (or, rather, by the devising of a set of rules which are consistent with the ways language is used), without examining the contents of the box.

Every field of cultural activity was affected by these doctrines that feared the identification of the mental and the material. Neokantianism introduced the idea that our perceptions are limited by our genetic endowment, and that as a result of that limitation, what we perceive is in reality only a symbolic abstraction.

In sociology, "symbolic interactionism," and in psychology, anthropology and linguistics various "structuralist" and "functionalist" doctrines offered antimaterialist ways to describe reality. Konrad Lorenz, serving as the theoretician of genocide, applied these ideas to anthropology and biology. Sociobiology and ethology are the current forms of Lorenz's doctrine. While symbolic interactionism has been used to justify cultural relativism, and sociobiology has been used to justify genocide, both of these seemingly opposite schools grew out of similar commitments to an abstracted and symbolic view of reality.

The school of "Artificial Intelligence" derives from, and is committed to, this immaterial, symbolic view of consciousness. The idea of "neural networks" would seem to have incorporated a material foundation, but actually it has only reassimilated the theoretical language that was used by the neurologists of the Eccles school of symbolic, immaterial, neurology. The image of a computer was imposed onto the brain, and then this theoretical description, in which "neural" no longer carried any substantial, metabolic meaning, was able to be used in its denatured form by the immaterialists.

In recent years, new technologies such as NMR/MRI have been able to show many metabolic details of the brain during different kinds of mental activity, and in different sicknesses. 25 years ago, N. P. Bekhtereva demonstrated that specific electrical patterns corresponding to a certain word or image could be identified in the brain, and recently the US CIA has funded research in which brain waves measured on the surface of the scalp can clearly show whether certain words or images have special significance for a person.

When the studies of brain chemistry and electrical activity are combined, it becomes clear that moods and meanings interact with metabolic processes in biologically rational ways, that have to do with adaptation of the organism to its environment. The "content" of our experience, and our substantial metabolism are so closely linked that there is no way to radically distinguish them.

R. D. Laing and Carl Rogers described the process of seeing the world as the client sees it, and they had valuable insights into the meanings of "psychopathology." But they still operated within a "symbolically constructed" reality, ignoring the metabolic, physiological aspects of their clients' problems.

The ability to perceive one's environment and adapt to it depends on having one's metabolic requirements met, and these chemical and physical issues are usually overlooked by psychiatrists, just as the issues of "meaning" may be overlooked by the physiologists.

Responding to particular people and particular demands can create organic and cellular patterns in which the glands, intestines, liver, nerves, and muscles adapt appropriately. The physiological pattern accomodates itself to the demands, but the organism's resources aren't always able to restore the original state, when the demands are no longer being made. Inadequate nutrition and inadequate stimulation limit adaptiveness, and create rigidity of behavior. Learned helplessness describes a global inability to adapt, that's produced by inescapable stress, but something like learned helplessness and unavoidable stress pervades our society, creating pathological rigidities.

The ability to perceive possibilities, and to act on those perceptions, requires biological resources, especially a high level of energy, but there must also be real possibilities in the environment. Several studies over the last forty years have shown that depressed and paranoid people have more accurate perceptions of their situation than happy optimists do.

The interlocking mental rigidities of millions of people are a problematic kind of adaptation. A

slight fluctuation in social relationships, such as losing a job or getting divorced, can cause tremendous changes in both perceived and real possibilities.

Dostoyevsky was interested in the "interlocking mental rigidities," and in various moral or spiritual alternatives. In Russian society, he said, psychopathology was the norm, lies could be therapeutic, and truth was the most poetic thing in the world ["Something about lying," 1873.] He used what might have been called, in the 20th century, themes of ***"anomie,"*** to explore consciousness and values. "Everything is meaningless," or "everything is lawful," instead of leading to suicide or crime, could lead to an exalted view of life's possibilities. Dostoyevski wrote about his own "nervous illness," that included alternating depression and ecstasy, and that has been considered to be some sort of epilepsy or schizophrenia. Whatever his mental illness was, he had a remarkable recovery when he was arrested and sent to prison. Before his arrest, he had been on a vegetarian diet, but in the prison in Siberia he was given a daily portion of hamburger.

Many people have experienced a dramatic improvement of mood when they began eating more protein. On a low protein or starvation diet, the body experiences, in different proportions, the "stress" reaction and the "hibernation" reaction.

An immediate reaction to hunger is to secrete adrenalin, which draws glucose from the liver and fats from the fatty tissues. When the liver's glycogen is depleted, cortisol is produced to mobilize amino acids from muscles and other tissues, to provide energy.

Muscle protein is very rich in tryptophan and cysteine, and these amino acids suppress the thyroid gland's function, and are potentially toxic to nerves, especially in the presence of cortisol and hypoglycemia. Tryptophan is turned into serotonin, which promotes lipid peroxidation, blood clotting, and certain patterns of nerve activity. Serotonin can suppress mitochondrial respiration, and along with the reduced body temperature that it produces, a pattern of torpor or helplessness tends to be produced.

But another pattern can be produced by stress, in which adrenaline and related substances maintain body temperature and alertness, despite the metabolic inefficiency. In hypothyroidism, it is common for adrenaline or noradrenaline to be produced in very large amounts. The brain and pituitary hormones (thyroid stimulating hormone, TSH, and its release hormone, TRH) that tend to increase in hypothyroidism, have their own brain modifying effects, increasing alertness and attention. Hypothyroidism can also cause hypersecretion of ACTH, adrenocorticotropin, which is also a powerful brain stimulant.

These two different reactions to stress, viz., torpor or tension, depression or hyper-alertness, are often seen as reactions to over-sleeping, or under-sleeping. On a Sunday, when a person sleeps an extra hour or two, it's common to feel lethargic for the rest of the day. And when a person has to get up several hours too early, there is often the feeling of being over-stimulated.

Many years ago, someone noticed that depressed people who missed a night's sleep, or who were wakened several hours earlier than normal, came out of their depression, until they caught up on their sleep. Sleep deprivation has become a recognized treatment for depression.

Manic-depressive ("bipolar") people typically seem to need very little sleep during their manic periods.

In depression, there is excessive influence of serotonin, in mania, excessive influence of adrenaline. These chemicals are links between energy metabolism and many specific adaptive physiological processes. One pattern of nerve activity, corresponding to these metabolic patterns, inclines a person to see the impossibility or futility of everything, the other causes an inclination to overlook impediments and undesirable consequences. In either state, important parts of reality are excluded.

Apart from these moods that can be induced by the interactions of diet, hormones, and the demands or opportunities of the envirnoment, the liveliness and vigor of metabolism influence the rhythms of thought and behavior, and the richness of experience and the appropriateness of activities. On a superficial level, our ability to

handle information can be compared to that of a computer, but that metaphor neglects our natural existence, that is like a vortex of biochemical and physical interactions, as well as being an assimilator and projector of impressions, meanings, and intentions. In a computer, the information being processed is separate from the hardware doing the processing, but in us, there is no information, message, content, or memory that is distinct from our living substance. Living substance isn't a collection of distinct objects that can be in this state or that state, because living substance is a process, always renewing itself with more or less appropriateness for its changing situations. Every state of consciousness is a state of being.

Let's look briefly at the way Anglo-American neurology came to look at the brain as a computer. For many years, the dogma said that the brain-computer was "hard wired," meaning that the arrangement of the nerves was genetically determined, set forever during fetal life, and altered only as individual nerve cells died during learning and aging. Since computer wires carried only on/off signals, nerves would carry only on/off signals: When a nerve "fired," it was said to be analogous to an "on-current," and the rest of the time it was "off." The nerve's electrical activity (contrary to clear evidence) was dogmatically identified with the superficial "lipid bilayer membrane," which was said to have only two states, open and closed. This abstract and incorrect description of an individual nerve was originally adopted because many neurologists, in the days before computers, wanted to be able to describe the brain as "a telephone swithchboard," handling messages, however, that were as simple as the patterned clicks of telegraphy. Information was one thing, the switching machinery was another thing.

The school of Pavlov (contrary to Anglo-American dogma) set out to understand consciousness, so when they thought of nerves, they avoided assumptions derived from telegraphy. There has never been any good reason to view nerves as wires carrying only simple "telegraphic" information. P. K. Anokhin, in his last book, discussed the reasons for believing that individual nerves handle complex information complexly. In practical fields, such as the physiology of hearing, there has been recognition that individual nerves seem to transmit qualitative, complex, messages.

The idea of a "hard-wired" computer-like brain was conditioned at every level by the philosophy of the immateriality of consciousness. The idea of telegraphic electrical impulses hardly changed when "neurotransmitter" chemicals were discovered: They just provided links between the filaments that still carried only on/off information. The idea that nerve cell metabolism ***is*** consciousness is still excuded from the ruling doctrine.

Since I have been interested in the way that hypothyroidism, a T3 deficiency, causes sleep problems, I have seen similar patterns in several seemingly different conditions. At menopause, insomnia, hypothyroidism, and diabetes are likely to develop along with hot flushes. Although hypothyroidism often causes the temperature to be subnormal, I saw many women whose temperature before breakfast was normal, but then fell after breakfast, usually following some hot flushes and sweats. Gradually, I began to realize that this corresponded to extremely high adrenalin and cortisol in the morning, and that high morning temperature was sometimes the first sign of the developing "hyper-alert" state, though most often it just represented the stress and exhaustion that result from disturbed, inefficient, sleep.

Using a small dose of T3 normally causes an increase of temperature and pulse rate, but in these people who are in an extremely adrenergic state, the T3 causes both the temperature and heart rate to decrease, as it restores metabolic efficiency. Then, as the stress state disappears, the thyroid supplements will gradually begin to bring the metabolic rate, temperature, and pulse up to normal. When a normal body temperature is maintained by thyroid-supported respiration, rather than by the stress hormones, sleep is efficient.

Thyroid, especially T3, has been commonly used in the treatment of depression, and there are many indications that, as it relieves the depression, it is also correcting a state of stress, lowering the cortisol which is typically

chronically increased in depression, and making sleep restful, rather than debilitating.

Women are especially susceptible to depression, diabetes, hypothyroidism, osteoporosis, Alzheimer's disease, and many other conditions that derive fairly directly from impaired energy metabolism. Some people have proposed that psychiatric problems are equivalent to "neural diabetes." "Syndrome X" (insulin resistance with heart symptoms) represents an advance toward seeing energy metabolism as the central biomedical issue.

Adequate dietary protein, and the ability to use it efficiently, should have the highest priority in the treatment and prevention of nervous and emotional problems, regardless of whether the diagnosis is "bipolar disorder," "depression," "schizophrenia," "multiple sclerosis," "obsessive compulsive disorder," or other official psychiatric category.

Without other nutrients, including sugar, much of the dietary protein is converted to energy, and without good thyroid function, protein can't be used properly. Whey, soy protein, and other industrial by-products sold as protein supplements aren't safe. Eating a variety of animal proteins, with some fruits and potatoes, is the safest way to prevent the metabolic disruptions caused by protein malnutrition.

Fortschr Neurol Psychiatr Grenzgeb 1975 Aug;43(8):381-440. **[Chronobiological aspects of cyclothymia].** Papousek M The paradoxical effect of sleep deprivation in endogenous depression has renewed the traditional interests of psychiatrists in the rhythmic phenomena associated with the symptomatology and course of cyclothymia. During the last decade, the rapid development of clinical research on sleep, neuroendocrinology, chromobiology and chronopathology in conjunction with important developments of methodology and statistical procedures have enabled a modern reconceptualization of the relationship between cyclothymia and disturbances in biological rhythms. An intensive review of the literature on circadian, ultradian, and infradian rhythms is reported here, and their relationship to the course and individual phases of cyclothymia is explored. The results of traditional analyses of sleep stages which had originally indicated that particular disturbances of sleep may be specific to cyclothymia have been shown to be incorrect. Rather, the abbreviation and fragmentation of sleep and the decrease of del asleep with concomitant increase in shallow stages have been found as well in serious sleep disturbances of other origins. Striking inter-and intra-individual variabilities in REM-sleep parameters characterize not only psychotic depression and severe mania but also a wide range of other acute psychoses...

Endocrinology 2000 Mar;141(3):1027-40. **Effects of pharmacological and nonpharmacological treatments on thyroid hormone metabolism and concentrations in rat brain.** Eravci M, Pinna G, Meinhold H, Baumgartner A. "The activities of the 5'I-deiodinase (5'D-I), 5'II deiodinase (5'D-II) and 5III-deiodinase (5D-III) isoenzymes and tissue concentrations of thyroxine (T4) and triiodothyronine (T3) were measured in up to 10 regions of the rat brain **after acute and subchronic nonpharmacological (sleep deprivation, 12 h fasting, 14 days' calorie-reduced diet)** and pharmacological (ethanol, haloperidol, clozapine, lithium, carbamazepine, desipramine, fluoxetine, tranylcypromine, and mianserin) treatments. All of these treatments induced significant and sometimes dramatic changes in 5'D-II activities and tissue concentrations of thyroid hormones and, to a lesser extent, in 5D-III activity. The activity of 5'D-I remained unaffected. The results revealed a surprising specificity for each type of treatment in terms of the isoenzyme and hormone affected, the direction of the change, the brain region affected and the time of day. The changes in thyroid hormone concentrations frequently failed to correspond in any way to those in deiodinase activities and unexpected effects such as inhibition of both 5'D-II and 5D-III were seen, indicating that there may be additional pathways of iodothyronine metabolism in the CNS. In conclusion, particularly 5'D-II activity and thyroid hormone concentrations in the CNS are highly sensitive to many different kinds of influence that may induce changes in neuronal activity. However, these changes in deiodinase activities do not ensure stable tissue concentrations of T3, but were, on the contrary, in most cases accompanied by marked changes T3 levels in the tissue."

WMJ 1995 Jan-Feb;67(1):105-11. **[Effect of nicotinamide on the uptake and release of serotonin and GABA by cerebral cortex synaptosomes in rats with diabetes induced by streptozotocin].** Donchenko GV, Kuchmerovskaia TM, Parkhomets PK, Obrosova IG, Klimenko AP, Efimov AS. Studies of neurotransmitter uptake and release by isolated rats brain cortex synaptosomes demonstrated that [2-14C]serotonin uptake was by 41% lower in streptozotocin-diabetic rats as compared to control. The [U-14C]GABA uptake was considerably elevated. [2-14C]serotonin and [U-14C]GABA release from the neurotransmitter pre-loaded synaptosomes showed significant elevation, especially during the first 3 minutes. Nicotinamide (NAm) administration (200 mg/kg body weight daily, 14 days) to diabetic rats restored synaptosomal serotonin uptake up to control levels....

J Endocrinol 1998 Feb;156(2):395-400 **Hypersecretion of corticotrophin-releasing hormone and arginine vasopressin in hypothyroid male rats as estimated with push-pull perfusion.** Tohei A, Watanabe G, Taya K. The relationship between hypothyroidism and disturbance of the hypothalamo-hypophysial-adrenal axis was investigated using adult male rats. Hypothyroidism was produced by administration of 4-methyl-2-thiouracil (thiouracil) in the drinking water for 2 weeks. Hypothyroidism decreased adrenal weights to 57% of controls and plasma concentrations of corticosterone to 48% of controls. The changes in the weight of adrenals recovered to control levels by administration of thyroxine. The pituitary responsiveness to corticotrophin-releasing hormone (CRH) and arginine vasopressin (AVP) for **ACTH release markedly increased in hypothyroid rats** as compared with euthyroid rats. In vivo release of CRH and AVP in median eminence significantly increased in hypothyroid rats as compared with euthyroid rats. There were no significant differences in hypothalamic concentrations of CRH and AVP. These results indicate that hypothyroidism causes adrenal dysfunction directly and results in hypersecretion of ACTH mediated by increases in synthesis of CRH and AVP in the hypothalamus.

September 2001

Intelligence and metabolism

Appropriate stimulation is an essential part of the developmental process. Inappropriate stimulation is a stress that deforms the process of growth. Mediators of stress, such as serotonin, can cause persistent distortions of physiology and behavior.

Education can either activate or suppress mental energy. If it is mainly obedience training, it suppresses energy. If it creates social dislocations, it disturbs mental and emotional energy.

Stress early in life can impair learning, cause aggressive or compulsive behavior, learned helplessness, shyness, alcoholism, and other problems.

Serotonin activates the glucocorticoid system, which can produce brain atrophy. Antiserotonin agents protect against brain atrophy and many other effects of stress. The brain-protecting neurosteroids, including pregnenolone and progesterone, which are increased by some kinds of stimulation, are decreased by isolation stress, and in their absence, serotonin and the glucocorticoids are relatively unopposed.

Since excess serotonin can cause thrombosis and vasospasms, and the excess cortisol resulting from hyperserotonemia can weaken blood vessels and the immune system, a person's longevity is likely to be shortened if something doesn't intervene to alter the patterns induced by stress early in life.

Having written about animal intelligence, and the ways in which it is similar to human intelligence, now I want those ideas to serve as a context for thinking about human intelligence without many of the usual preconceptions.

Intelligence is an interface between physiology and the environment, so it's necessary to think about each aspect in relation to the other. Things, both biochemical and social, that enhance intelligence enhance life itself, and vice versa.

Psychologists have tried to give their own definitions to words like idiot, imbecile, moron, and genius, but they have just been refining the clichés of the culture, in which "dummy" is one of the first words that kids in the U.S. learn. Many psychologists have tried to create "culture-free" tests of intelligence, making it clear that they believe in something like innate animal intelligence, though they usually call it "genetic" intelligence. Other psychometrists have transcended not only biology but even rationality, and have catalogued the ***preferences*** of people that they define as intelligent, and designed "I.Q. tests" based on the selection of things that were preferred by "intelligent people." This behavior is remarkably similar to the "psychometry" of the general culture, in which "smart" people are those who do things the "right" way.

Baroness Blatch: "My Lords, the levels of achievement are well above the national average of our own state schools."

"This is a school which attained 75 per cent A to C passes in 1998, and 63.9 per cent in 1999. Those figures are well above national averages. There is no truancy; and there is the highest possible level of parental satisfaction with the school. When those parents are paying their money and know what they are paying for, who are we to take a different view about the philosophy of education in a private school?"

Comment during debate in House of Lords, June 30, 1999, on Chief Inspector of Schools Woodhead's threat to close Summerhill, a democratic school which had been started in 1921.

In 1927, the government inspectors had recommended that 'all educationalists' should come to Summerhill to see its 'invaluable' research, which demonstrated that students' development is better when they regulate themselves and are not required to attend lessons.

About thirty years ago, someone found that the speed with which the iris contracts in response to a flash of light corresponds very closely to the I.Q. measured by a psychologist using a standard

intelligence test. The devices used to measure reaction time in drivers' education courses also give a good indication of a person's intelligence, but so does measuring their heart rate, or taking their temperature. Colleges would probably be embarrassed to admit students on the basis of their temperature (though they commonly award scholarships on the basis of the ability to throw a ball). Colleges, to the extent that they are serious about the business of education, are interested in the student's ability to master the culture.

The way a person has learned during childhood can shape that person's manner of grasping the culture. To simply accelerate the learning of a standard curriculum will increase that person's "I.Q." on a conventional test, but the important issue is whether it is really intelligent to learn and to value the things taught in those curricula. Some educators say that their purpose is to socialize and indoctrinate the students into their discipline, others believe their purpose is to help their students to develop their minds. Both of these approaches may operate within the idea that "the culture" is something like a museum, and that students should become curators of the collection, or of some part of it. If we see the culture metaphorically as a mixture of madhouse, prison, factory, and theater, the idea of "developing the student's mind" will suggest very different methods and different attitudes toward "the curriculum"

Even sophisticated people can fall into stereotyped thinking when they write about issues of intelligence. For example, no one considers it a sign of genius when a slum kid is fluent in both Spanish and English, but when some of history's brightest people are discussed, the fact that they learned classical Greek at an early age is always mentioned. No one mentions whether they were competent in idiomatic Spanish.

One of the old cultural stereotypes is that child prodigies always "burn out," as if they were consuming a fixed amount of mental energy at an accelerated rate. (This idea of burn-out is isomorphic with the other cultural stereotypes relating aging to the "rate of living," for example that people with slow heart beats will live longer.) Some of the men who have been considered as the world's brightest have, in fact, gone through a crisis of depression, and Terman's long-term study of bright people found that "maladjustment" did increase with I.Q., especially among women. But the facts don't support the concept of "burn-out" at all. I think the facts reveal instead a deep flaw in our ideas of education and professional knowledge.

In a world run by corporation executives, university presidents ("football is central to the university's mission"), congressmen, bankers, oilmen, and agency bureaucrats, people with the intelligence of an ant (a warm ant) might seem outlandishly intelligent. This is because the benighted self-interest of the self-appointed ruling class recognizes that objective reality is always a threat to their interests. If people, for example, realized that estrogen therapy and serotonin-active drugs and x-rays and nuclear power and atomic bomb tests were beneficial only to those whose wealth and power derive from them, the whole system would lose stability. Feigned stupidity becomes real stupidity.

But apart from ideologically institutionalized stupidity, there are real variations in the ability to learn, to remember and to apply knowledge, and to solve problems. These variations are generally metabolic differences, and so will change according to circumstances that affect metabolism. Everyday social experiences affect metabolism, stimulating and supporting some kinds of brain activity, suppressing and punishing others. All of the activities in the child's environment are educational, in one way or another.

Some of the famous prodigies of history illustrate the importance of ideology in the development of intellect. Family ideology, passing on the philosophical orientations of parents and their friends, shapes the way the children are educated.

Some of these family traditions can be traced by considering who the child's godfather was. Jeremy Bentham was John Stuart Mill's godfather, Mill was Bertrand Russell's; Ralph Waldo Emerson was William James' godfather, James was W. J. Sidis's. Willy Sidis was educated by his parents to demonstrate their theory of education, which grew out of the philosophies of Emerson and James. His father, Boris Sidis, was a

pioneer in the study of hypnosis, and he believed that suggestion could mobilize the mind's "reserve energy." Willy learned several languages and advanced mathematics at an early age. After he graduated from Harvard at the age of 16, he tried teaching math at Rice Institute, but he was displeased by the attitudes of his students and of the newspaper and magazine writers who made a profession of mocking him. He attended law school at Harvard, and would have been imprisoned as a conscientious objector if the war hadn't ended.

Antisemitism probably played a role in his sense of isolation when he was at Harvard and Rice. In 1912 Henry Goddard, a pioneer in intelligence testing (and author of ***The Kallikak Family: A Study in the Heredity of Feeble- Mindedness***), administered intelligence tests to immigrants and determined that 83 percent of Jews and 87 percent of Russians were "feeble-minded." By the standards of the time, it was highly inappropriate for the child of extremely poor Jewish immigrants from eastern Europe to be so bright.

Sidis hid from the press, and worked as a bookkeeper and clerk, while he studied and wrote. During his years of obscurity, he wrote books on philosophy and American history. Eventually, the journalists discovered him again, and after prolonged lawsuits against the magazines for invasion of privacy and slander, he died of a stroke at the age of 46.

Sidis is probably the culture's favorite example of the child prodigy who burns out, but people (Robert Persig, Buckminster Fuller) who have read his books have said favorable things about them. The journalists' emphasis on the fact that Sidis never held a prestigious job nicely illustrates their cliché mentality: "If you're so smart, why aren't you rich?" But throughout history, intelligent nonconformists have supported themselves as craft-workers or technicians--Socrates as a stone mason, Spinoza as a lens grinder, Blake as an engraver, Einstein as a patent examiner, for example.

In conventional schools (as in conventional society) 10,000 questions go unanswered, not only because a teacher with many students has no time to answer them, but also because most teachers wouldn't know most of the answers.

The parents of W. J. Sidis and J. S. Mill were remarkably well educated people who, because they dissented from society's ideology, chose to spend much of their time educating their children. Whenever a question about Euclidean geometry or Greek grammar occurred to the child, it could be answered immediately. It was only natural that progress would be fast, but there were more important differences.

When questions are answered, curiosity is rewarded, and the person is enlivened. In school, when following instructions and conforming to a routine is the main business, many questions must go unanswered, and curiosity is punished by the dulling emptiness of the routine.

Some schools are worse than others. For example, slum children were given I.Q. tests when they started school, and each subsequent year, and their I.Q.s dropped with each year of school. In a stimulating environment, the reverse can happen, the I.Q. can rise each year. Since the tests aren't "culture free," their scores reflected the material that they were being taught, but they undoubtedly also reflected the increasing boredom and despair of the children in a bad school, or the increasing liveliness of the children in the stimulating environment.

I have spoken with people in recent years who still held the idea of a fixed genetic mental potential, who believe that poor children fall behind because they are reaching their "genetic limit." For them, the I.Q. represents an index of intrinsic quality, and is as important as distinguishing between caviar and frogs' eggs. The rat research of Marion Diamond and others at the University of California, however, showed that the structure, weight, and biochemistry of a rat's brain changes, according to the amount of environmental stimulation and opportunity for exploration. This improvement of brain structure and function is passed on to the next generation, giving it a head-start. It isn't likely that rats are more disposed than humans to benefit from mental activity, and in the years since Diamond's research there have been many discoveries showing that brains of all

sorts complexify structurally and functionally in response to stimulation.

Rats isolated in little boxes, generation after generation--the normal laboratory rats--were the standard, but now it's known that isolation is a stress that alters brain chemistry and function.

Willy Sidis and John Stuart Mill were being stimulated and allowed to develop in one direction, but they were being isolated from interaction with their peers. When Mill was twenty he went into a depression, and later he wrote that it was because he discovered that he was unable to ***feel.*** He had developed only part of his personality.

Bertrand Russell (1872-1970), orphaned at the age of four, went to live with his grandmother, who chose not to send him to school, but provided tutors. He didn't experience a sense of academic pressure, and was able to read whatever he wanted in his late grandfather's library. He didn't realize that he was unusually bright until he went to Cambridge. The unusual freedom of his childhood must have contributed to his willingness to hold unpopular opinions. In 1916 he was fined, and in 1918 imprisoned for 6 months, for opposing the war.

In 1927, Russell and his wife, Dora Black, started a school. He later wrote that, although the average student at the school was very bright, an exceptionally bright student was likely to be ostracized by the less bright students. He commented on the harm done to the brightest students by their social isolation, probably thinking about his own education in relative isolation. A psychologist (Leta Hollingworth, 1942) has made similar observations about the isolation that can be produced by a large difference of I.Q. She did a series of studies of very bright children, beginning in 1916, including working with some of them in a program she designed in a New York public school. Her empathy allowed her to discover things that weren't apparent to her contemporaries.

During this time Lewis Terman was studying bright children, and wanted to disprove some of the popular stereotypes about intelligent people, and to support his ideology of white racial superiority. In 1922 he got a large grant, and sorted out about 1500 of the brightest children from a group of 250,000 in California. He and his associates then monitored them for the rest of their lives (described in ***Genetic Studies of Genius***). His work contradicted the stereotype of bright people as being sickly or frail, but, contrary to his expectation, there was an association between maladjustment and higher I.Q.; the incidence of neurotic fatigue, anxiety, and depression increased along with the I.Q. The least bright of his group were more successful in many ways than the most bright. He didn't really confront the implications of this, though it seriously challenged his belief in a simple genetic racial superiority of physique, intellect, and character.

I.Q. testing originated in a historical setting in which its purpose was often to establish a claim of racial superiority, or to justify sterilization or "euthanasia," or to exclude immigrants. More recently, the tests have been used to assign students to certain career paths. Because of their use by people in power to control others, the I.Q. tests have helped to create misunderstanding of the nature of intelligence. A person's "I.Q." now has very strong associations with the ideology of schooling as a road to financial success, rather than to enrichment of a shared mental life.

If a bad school resembles, on the intellectual level, a confining rat box, the educational isolation of Mill, Russell, and Sidis was emotionally limiting, almost like solitary confinement. Once when Willy Sidis was arrested for marching in a May Day parade, his father was able to keep him from going to prison, but Willy apparently would have preferred the real prison to life with his parents.

None of these three famous intellects was known for youthful playfulness, though playfulness is a quality that's closely associated with intelligence in mammals and birds. (Russell, however, in middle age developed many new interests, such as writing short stories, and had many new loves even in old age.) Stress early in life, such as isolation, reduces the playfulness of experimental animals. Playfulness is contagious, but so is the inability to play.

In schools like Summerhill, which was founded in 1921 by A. S. Neill, students aren't

required to attend classes when they would rather do something else, but at graduation they usually do better on their standardized national examinations than students who have dutifully attended classes for years. For students, as for rats, freedom and variety are good for the brain, and tedious conformity is harmful. When a school is very good, it can spread a contagion of playfulness along with an interest in learning.

An environment that fosters optimal intelligence will necessarily promote the development of emotional health, and will almost certainly foster good physical health and longevity, because no part of the physiological system can thrive at the expense of another part. And within the boundaries of life-enriching environments, there are infinite possibilities for variety.

There is a common belief in the rigidity of the adult nervous system, in analogy with feral cats or dogs, that supposedly can't be tamed if they have grown up without knowing humans. But people who have had the inclination to understand wild animals have found that, even when the animals have been captured as adults, they can become as sociable as if they had grown up in domestication. The "horse whisperer" demonstrated this sort of empathetic approach to animals. Sometimes, these people have a similar ability to communicate with people who are retarded, or autistic, or demented, but the professionalization of society has made it increasingly unlikely that people with the need for intuitive help will encounter someone who is able to give it. The closest psychology has come to professionally recognizing the importance of empathy was in Carl Rogers' work, e.g., *Client-Centered Therapy.*

Rogers showed that a sense of solidarity must exist between therapist and client for the therapy to be helpful. A similar solidarity has to exist between teacher and student, for education to be successful. If ordinary family and social contacts could occur within such an atmosphere of mutual respect, psychopathology (including learning difficulties) would be much less common.

Although three individuals don't prove an argument, I think the lives and situations of Sidis, Mill, and Russell are usefully symbolic. Sidis, who grew up under intense pressure and social isolation and in extreme poverty, died at the age of 46. Mill, who was educated mainly by his father, in secure financial circumstances, experienced social isolation and moderate pressure, and lived about 20 years longer than Sidis did. Russell, who grew up in the highest circles of the ruling class, experienced no pressure, and only the mild kind of social isolation that wasn't exceptional for his class. He lived to be 97.

The psychopathology of social isolation has been studied in a variety of animals, and many features are similar across species, including humans. Aggression, helplessness, and reduced ability to learn are typically produced in animals by social isolation, and it's clear that certain kinds of family environment produce the same conditions in children. Schools seldom help, and often hinder, recovery from such early experiences.

"Vital exhaustion," decreased slow wave sleep, and anger, which are associated with the "type A personality" and with circulatory and heart disease, appear to have their origin in childhood experiences. Low income and financial insecurity are strongly associated with anger, sleep disturbances, and circulatory disease. In animals stressed by social isolation, similar features emerge, under the influence of decreased neurosteroids, and increased serotonin and activity of the glucocorticoid system.

The "smart drug" culture has generally been thinking pharmaceutically rather than biologically. Behind that pharmaceutical orientation there is sometimes the idea that the individual just isn't trying hard enough, or doesn't have quite the right genes to excel mentally.

Many stimulants--amphetamine and estrogen, for example--can increase alertness temporarily, but at the expense of long range damage. The first principle of stimulation should be to avoid a harmful activation of the catabolic stress hormones. Light, play, environmental variety and exploratory conversations stimulate the whole organism in an integral way, stimulating repair processes and developmental processes.

Any chemical support for intelligence should take into account the mind-damaging stresses that our culture can impose, and provide defense

against those. In darkness and isolation, for example, the stress hormones increase, and the brain-protective steroids decrease. The memory improvement that results from taking pregnenolone or thyroid (which is needed for synthesizing pregnenolone from cholesterol) is the result of turning off the dulling and brain-dissolving stress hormones, allowing normal responsiveness to be restored.

If we know that rats nurtured in freedom, in an interesting environment, grow more intelligent, then it would seem obvious that we should experiment with similar approaches for children--if we are really interested in fostering intelligence. And since violence and mental dullness are created by the same social stresses, even the desire to reduce school violence might force the society to make some improvements that will, as a side effect, foster intelligence.

Eur J Pharmacol 1992 Feb 25;212(1):73-8. **5-HT3 receptor antagonists reverse helpless behaviour in rats.** Martin P, Gozlan H, Puech AJ Departement de Pharmacologie, Faculte de Medecine Pitie-Salpetriere, Paris, France. The effects of the 5-HT3 receptor antagonists, zacopride, ondansetron and ICS 205-930, were investigated in an animal model of depression, the learned helplessness test. Rats previously subjected to a session of 60 inescapable foot-shocks exhibited a deficit of escape performance in three subsequent shuttle-box sessions. The 5-HT3 receptor antagonists administered i.p. twice daily on a chronic schedule (zacopride 0.03-2 mg/kg per day; ondansetron and ICS 205-930: 0.125-2 mg/kg per day) reduced the number of escape failures at low to moderate daily doses. This effect was not observed with the highest dose(s) of zacopride, ondansetron and ICS 205-930 tested. These results indicate that 5-HT3 antagonists may have effects like those of conventional antidepressants in rats.

Neuropharmacology 1992 Apr;31(4):323-30. **Presynaptic serotonin mechanisms in rats subjected to inescapable shock.** Edwards E, Kornrich W, Houtten PV, Henn FA. "After exposure to uncontrollable shock training, two distinct groups

of rats can be defined in terms of their performance in learning to escape from a controllable stress. Learned helpless rats do not learn to terminate the controllable stress, whereas non-learned helpless rats learn this response as readily as naive control rats do." "These results implicate presynaptic serotonin mechanisms in the behavioral deficit caused by uncontrollable shock. In addition, a limbic-hypothalamic pathway may serve as a control center for the behavioral response to stress."

Neurochem Int 1992 Jul;21(1):29-35. **In vitro neurotransmitter release in an animal model of depression**. Edwards E, Kornrich W, van Houtten P, Henn FA. "Sprague-Dawley rats exposed to uncontrollable shock can be separated by a subsequent shock escape test into two groups: a "helpless" (LH) group which demonstrates a deficit in escape behavior, and a "nonlearned helpless" (NLH) group which shows no escape deficit and acquires the escape response as readily as naive control rats (NC) do." "The major finding concerned a significant increase in endogenous and K(+)-stimulated serotonin (5-HT) release in the hippocampal slices of LH rats. There were no apparent differences in acetylcholine, dopamine and noradrenaline release in the hippocampus of LH rats as compared to NLH and NC rats. These results add further support to previous studies in our laboratory which implicate presynaptic 5-HT mechanisms in the behavioral deficit caused by uncontrollable shock."

Psychiatry Res 1994 Jun;52(3):285-93. **In vivo serotonin release and learned helplessness.** Petty F, Kramer G, Wilson L, Jordan S Mental Health Clinic, Dallas Veterans Affairs Medical Center, TX. Learned helplessness, a behavioral depression caused by exposure to inescapable stress, is considered to be an animal model of human depressive disorder. Like human depression, learned helplessness has been associated with a defect in serotonergic function, but the nature of this relationship is not entirely clear. We have used in vivo microdialysis brain perfusion to measure serotonin (5-hydroxytryptamine, 5HT) in extracellular space of medial frontal cortex in conscious, freely moving rats. Basal 5HT levels in rats perfused before exposure to tail-shock stress did not themselves correlate with subsequent learned helplessness behavior. However, 5HT release after stress showed a significant increase with helpless behavior. **These data support the hypothesis that a cortical serotonergic excess is causally related to the development of learned helplessness.**

Pharmacol Biochem Behav 1994 Jul;48(3):671-6. **Does learned helplessness induction by haloperidol involve serotonin mediation?** Petty F, Kramer G, Moeller M Veterans Affairs Medical Center, Dallas 75216. Learned helplessness (LH) is a behavioral depression following inescapable stress. Helpless behavior was induced in naive rats by the dopamine D2 receptor blocker haloperidol (HDL) in a dose-dependent manner, with the greatest effects seen at 20 mg/kg (IP). Rats were tested 24 h after injection. Haloperidol (IP) increased release of serotonin (5-HT) in medial prefrontal cortex (MPC) as measured by in vivo microdialysis. Perfusion of HDL through the probe in MPC caused increased cortical 5-HT release, as did perfusion of both dopamine and the dopamine agonist apomorphine. Our previous work found that increased 5-HT release in MPC correlates with the development of LH. The present work suggests that increased DA release in MPC, known to occur with both inescapable stress and with HDL, may play a necessary but not sufficient role in the development of LH. Also, this suggests that increased DA activity in MPC leads to increased 5-HT release in MPC and to subsequent behavioral depression.

Arzneimittelforschung 1975 Nov; 25(11):1737-44. **[Central action of WA-335-BS, a substance with peripheral antiserotonin and antihistaminic activity].** Kahling J, Ziegler H, Ballhause H. "In rats and mice the serotonin and histamine antagonistic drug . . . (WA 335-BS) caused stronger central sedative effects than did cyproheptadine. WA 335-BS also displayed stronger activity against reserpine- and central tremorine-induced effects than did cyproheptadine and it slightly enhanced d-amphetamine-induced effects: **therefore it may have antidepressant properties. WA 335-BS proved to be very effective against isolation-induced aggression in male mice.** The comparatively small anxiolytic effects may have been caused in part by the central antiserotonin properties." "The results of our animal studies suggest WA 335-BS to be an antidepressant with sedative properties."

"Rearing rats in isolation has been shown to be a relevant paradigm for studying early life stress and **understanding the genesis of depression and related affective disorders.** Recent studies from our laboratory point to the relevance of studying the social isolation syndrome as a function of home caging conditions."

Stroke 1991 Nov;22(11):1448-51. **Platelet secretory products may contribute to neuronal injury.** Joseph R, Tsering C, Grunfeld S, Welch KM. BACKGROUND: We do not fully understand the mechanisms for neuronal

damage following cerebral arterial occlusion by a thrombus that consists mainly of platelets. The view that certain endogenous substances, such as glutamate, may also contribute to neuronal injury is now reasonably well established. Blood platelets are known to contain and secrete a number of substances that have been associated with neuronal dysfunction. Therefore, we hypothesize that a high concentration (approximately several thousand-fold higher than in plasma, in our estimation) of locally released platelet secretory products derived from the causative thrombus may contribute to neuronal injury and promote reactive gliosis. SUMMARY OF COMMENT: We have recently been able to report some direct support for this concept. When organotypic spinal cord cultures were exposed to platelet and platelet products, a significant reduction in the number and the size of the surviving neurons occurred in comparison with those in controls. We further observed that serotonin, a major platelet product, has neurotoxic properties. There may be other platelet components with similar effect. **CONCLUSIONS: The hypothesis of platelet-mediated neurotoxicity gains some support from these recent in vitro findings. The concept could provide a new area of research in stroke, both at the clinical and basic levels.**

Am J Psychiatry 1981 Aug;138(8):1082-5. **Tryptophan metabolism in children with attentional deficit disorder.** Irwin M, Belendiuk K, McCloskey K, Freedman DX The authors present the first report, to their knowledge, of hyperserotonemia in children with attentional deficit disorder who had normal intelligence. Hyperserotonemic children had significantly lower levels of plasma total and protein-bound tryptophan and a higher percentage of free tryptophan than those with normal serotonin levels. Plasma kynurenine did not differ, suggesting that the hyperserotonemia is not due to a blockade of the kynurenine pathway but may reflect on increase in tissue tryptophan uptake and use.

"Administration of serotonin into the lateral ventricle of the brain of male rats, against the background of complete isolation of the medial-basal hypothalamus was accompanied by the block of the compensatory elevation of the blood testosterone level following unilateral castration."

Encephale 1994 Sep-Oct;20(5):521-5. **[Can a serotonin uptake agonist be an authentic antidepressant? Results of a multicenter, multinational therapeutic trial].** Kamoun A, Delalleau B, Ozun M The classical biochemical hypothesis of depression posits a functional deficit in central neurotransmitter systems particularly serotonin (5-HT) and noradrenaline. The major role suggested for 5-HT in this theory led to the development of a large number of compounds which selectively inhibit 5-HT uptake. Numerous clinical trials have demonstrated the antidepressant efficacy of such types of serotoninergic agents, supporting 5-HT deficit as the main origin of depression. **Therefore, everything seemed clear: depression was caused by 5-HT deficit. Tianeptine is clearly active in classical animal models predictive of antidepressant activity, and is also active in behavioral screening tests: it antagonizes isolation induced**

aggression in mice and behavioral despair in rats. Biochemical studies have revealed that in contrast to classical tricyclic antidepressant, **tianeptine stimulates 5-HT uptake** in vivo in the rat brain. This somewhat surprising property was observed in the cortex and the hippocampus following both acute and chronic administrations. This increase in 5-HT uptake has also been confirmed in rat platelets after acute and **chronic administrations. Moreover, in humans, a study in depressed patients demonstrated that tianeptine significantly increased platelet 5-HT uptake after a single administration as well as after 10 and 28 days of treatment. The antidepressant activity of tianeptine has been evaluated in controlled studies versus reference antidepressants. Another study aiming to compare the antidepressant efficacy of tianeptine versus placebo and versus imiporamine is** presented. 186 depressed patients were included in this trial. They presented with either Major Depression, single episode (24.6%) or Major Depression recurrent (66.8%) or Bipolar Disorder (depressed) (8.6%).

Psychopharmacology (Berl) 1998 Oct;139(3):255-60. **Ca2+ dependency of serotonin and dopamine release from CNS slices of chronically isolated rats.** Jaffe EH. "We have used chronic isolated housing as an animal model of depression." "The following questions were addressed: first, if there is a change in the depolarization dependent release of DA and 5-HT from these CNS structures, and second, if the release is through the classical exocytotic mechanism. **A significant increase in KCl stimulated release of 5-HT was observed in chronically isolated animals when compared to controls.** 5-HT release was completely abolished from controls or isolated animals, when slices were incubated with Krebs containing zero Ca2+/10 mM Mg2+, the inorganic Ca2+ channel blockers, Cd2+ or Ni2+ and the calmodulin inhibitor, trifluoperazine." **"The basal release of DA and 5-HT was similar in control and isolated animals and was not affected by the Ca2+ channel antagonists. The results suggest that extracellular Ca2+-dependent release of 5-HT and, to a lesser degree, of DA, is increased in this chronic animal model of depression in** several CNS structures."

Gen Pharmacol 1994 Oct;25(6):1257-1262. **Serotonin-induced decrease in brain ATP, stimulation of brain anaerobic glycolysis and elevation of plasma hemoglobin; the protective action of calmodulin antagonists.** Koren-Schwartzer N, Chen-Zion M, Ben-Porat H, Beitner R Department of Life Sciences, Bar-Ilan University, Ramat Gan, Israel. **1. Injection of serotonin (5-hydroxytryptamine) to rats, induced a dramatic fall in brain ATP level, accompanied by an increase in P(i). Concomitant to these changes, the activity of cytosolic phosphofructokinase, the rate-limiting enzyme of glycolysis, was significantly enhanced. Stimulation of anaerobic glycolysis was also reflected by a marked increase in lactate content in brain. 2. Brain glucose** 1,6-bisphosphate level was decreased, whereas fructose 2,6-bisphosphate was unaffected by serotonin. 3. All these serotonin-induced changes in brain, which are characteristic for cerebral ischemia, were prevented by treatment with the calmodulin (CaM) antagonists, trifluoperazine or thioridazine. **4. Injection of serotonin also induced a marked elevation of plasma hemoglobin, reflecting lysed erythrocytes,** which was also prevented by treatment with the CaM antagonists. 5. **The present results suggest that CaM antagonists may be effective drugs in treatment of many pathological conditions and diseases in which plasma serotonin levels are known to increase.**

Eur Neuropsychopharmacol 1997 Oct;7 Suppl 3:S323-S328. **Prevention of stress-induced morphological and cognitive consequences.** McEwen BS, Conrad CD, Kuroda Y, Frankfurt M, Magarinos AM, McKittrick C. Atrophy and dysfunction of the human hippocampus is a feature of aging in some individuals, and this dysfunction predicts later dementia. There is reason to believe that adrenal glucocorticoids may contribute to these changes, since the elevations of glucocorticoids in Cushing's syndrome and during normal aging are associated with atrophy of the entire hippocampal formation in humans and are linked to deficits in short-term verbal memory. We have developed a model of stress-induced atrophy of the hippocampus of rats at the cellular level, and we have been investigating underlying mechanisms in search of agents that will block the atrophy. Repeated restraint stress in rats for 3 weeks causes changes in the hippocampal formation that include suppression of 5-HT1A receptor binding and atrophy of dendrites of CA3 pyramidal neurons, as well as impairment of initial learning of a radial arm maze task. **Because serotonin is released by stressors and may play a role in the actions of stress on nerve cells, we investigated the actions of agents that facilitate or inhibit serotonin reuptake.** Tianeptine is known to enhance serotonin uptake, and we compared it with fluoxetine, an inhibitor of 5-HT reuptake, as well as with desipramine. **Tianeptine treatment (10 mg/kg/day) prevented the stress-induced atrophy of dendrites of CA3 pycamidal neurons,** whereas neither fluoxetine (10 mg/kg/day) nor desipramine (10 mg/kg/day) had any effect. **Tianeptine treatment also prevented the stress-induced impairment of radial maze learning.** Because **corticosterone- and stress-induced atrophy of CA3 dendrites is also blocked by phenytoin, an inhibitor of excitatory amino acid release and actions, these results suggest that serotonin released by stress or corticosterone may interact pre- or post-synaptically with glutamate released by stress or corticosterone, and that the final common path may involve interactive effects between serotonin and glutamate receptors on the dendrites of CA3 neurons innervated by mossy fibers from the dentate gyrus. We discuss the implications of these findings for treating cognitive impairments and the risk for dementia in the elderly.**

"Cocaine babies," criminal responsibility, and medicine

In the 1950s and later, the US medical establishment was still arguing for the safety of prenatal x-rays.

Through the 1950s and 1960s the U.S Atomic Energy Commission and the medical profession collaborated in keeping the public from knowing the dangers of prenatal exposures to harmful influences, including drugs, diet, and radiation. Childhood cancer and brain defects were produced in millions of children as a result. Fetotoxic drugs are still in use by physicians.

The problem is, partly, that medicine is not a biological science. It is a profession, meaning that whatever it professes to know has the legal status of truth.

Problem-centered ecological health education would be a step toward solution of the problems of public health.

Many pregnant women have been prosecuted for "delivering an illegal drug to their fetus" when they use cocaine.

If a person chooses to believe something that's contrary to the best evidence, when they are aware of the evidence, that can be called faith. But when their behavior harms others, their willful ignorance becomes a moral issue.

When the medical profession starts to get something right, a century after researchers had clarified the facts, the general euphoria should be tempered by what is actually happening. The medical profession is now concerned about the harmful effects of using cocaine and alcohol in pregnancy. Exactly what does this new seemingly realistic attitude mean? What could motivate this great new interest in the well-being of the fetus? Why are these substances the focus of such concern? I'm afraid it is purely because these are all self-administered substances, and the blame can be placed on the user, rather than on any powerful institutions.

Just 30 years ago, the conventional wisdom was that the fetus is isolated and insulated from the mother's metabolism. The thalidomide episode was already forcing doctors to acknowledge that ***some*** drugs might get through the placenta, though the drug industry was reluctant to lose the pregnant-woman market.

"The legal responses to the "crack baby scare" clearly did much more harm than good to both the mothers and the children. Making substance abuse during pregnancy a crime kept mothers from prenatal medical care, thereby endangering the fetus far more than would be the case with drug use, and discouraged them from seeking drug treatment."

". . . the fact remains that recent studies on cocaine use by pregnant women clearly demonstrate that the pharmacological impact of cocaine has been greatly exaggerated, that many other factors impact on fetal and newborn development, and that legal responses to maternal cocaine use have made every aspect of the problem worse."

Gary Potter
Professor, Police Studies
Eastern Kentucky University

The idea that fetal damage could result from the mother's malnutrition was rejected as an impossibility. The food industry didn't want to have to test their GRAS (generally recognized as safe) additives for fetal safety, and it didn't want women to get the idea that they should avoid junk foods, such as pasta and bread, during pregnancy. People at the Harvard School of Public Health said that it was nonsense to think that foods could

be nutrient-deficient--"if the soil doesn't have the chemicals plants need, the plants won't grow; therefore, all crops are fully nutritious." The chemical composition of plants was supposedly determined strictly by their genes, so the soil couldn't determine their nutrient content. The fetus, like a plant, was supposed to be genetically determined, but unlike a plant, it was said to live like a parasite on the mother, taking everything it needs from the mother's tissues, rather than from the mother's dietetic intake. If the mother was alive, her nutritional condition couldn't have anything to do with the fetus.

Probably in reaction against the biological evidence that maternal malnutrition produced defective offspring, the American medical establishment adopted the concept that "fetal malnutrition" existed, and was caused by a defective uterus or placenta, not by anything the mother might have eaten or failed to eat. In Italy and Germany in the 1970s, a slightly saner concept was emerging, in which it was proposed that a malnourished fetus could be fed by infusing amino acids into the amniotic fluid, or that the mother and fetus might benefit from intravenous glucose and amino acids. The use of progestins to stimulate placental development was also suggested in Europe. (Farad and Picas, 1976.)

Poor, illiterate, drug using women are now being charged with "giving cocaine to their fetus" when they use the drug. What this means is that there are elements in our judicial system which are saying that illiterates and derelicts must be held to a higher standard than doctors of medicine were when these women were children--and to a higher standard than that of the present state licensing boards which have nothing to say to physicians who prescribe reducing diets and diuretics and teratogenic drugs, and even x-rays, to pregnant women.

Several articles on cocaine babies have emphasized the huge cost resulting from their health care. I have never seen a discussion of the economics of the damage caused by medical and governmental aggressions against the public. If the cost to the public of caring for cocaine babies is the important issue, then we should consider the cost of preventing the damage in the most direct way, but that requires knowing what the real causes of the damage are.

The evidence that these babies' defects are caused by cocaine is fairly odd. Being scientifically careful about evaluating the evidence in this situation is important, considering the history and the context.

In the late 1960s, most of the publications on the dangers of LSD and marihuana were fraudulent. While typical LSD users took about 100 micrograms of the drug, experiments using doses that were the human equivalent of tens of thousands of micrograms were used to argue for the drug's dangers. Those doses would have killed people, in a short time.

In humans, as little as 20 milligrams of cocaine injected intravenously is said to have been fatal, and the average lethal ***oral*** dose is 500 milligrams. Injected cocaine is much more powerful than oral doses. **In animal studies, doses equivalent to thousands of milligrams per day in humans are injected into rats before harmful effects are seen in the fetuses.** Drugs injected intravenously or injected into the peritoneal cavity are very rapidly and completely absorbed, and the only doses that caused measurable fetal harm in rats were doses that, on a weight basis, almost certainly would have caused nearly instantaneous death in humans.

Cocaine suppresses appetite. When pregnant animals are fed the same limited amount of food consumed by cocaine-treated animals, their undernourished offspring show most of the same effects seen in the litters that were exposed to cocaine.

The human placenta passes a smaller percentage of cocaine to the fetus than the rat placenta does, and the liver of the human fetus is more effective at detoxifying cocaine, so any effects of cocaine on rat fetuses are probably going to be larger than any effect on the human fetus.

Behavioral disturbances in the offspring are considered to be a very sensitive indicator of a chemical's teratogenicity, but some researchers have concluded that cocaine might not be a behavioral teratogen. (Riley and LaFiette, 1996) Others have described it as "not a potent neuroteratogen." (Chen, et al., 1996)

The effects of cocaine that are supposedly seen in humans seem not to be produced by cocaine in lab animals. Intrauterine growth retardation, microencephaly, abruptio placentae, spontaneous abortion, sudden infant death syndrome, and mental retardation are commonly said to be the consequences of prenatal exposure to cocaine. Many things can contribute to those problems, but malnutrition is the most common cause, and is the one that American medicine goes to great lengths to avoid mentioning. Prenatal x-rays, diuretics, and pregnancy weight-control diets are other important causes.

How is it that cocaine and starvation can produce the same symptoms? I think the evidence indicates that cocaine isn't the cause of the pregnancy problems that are blamed on it. But, since cocaine suppresses the appetite, it does have some role in the problems of gestation caused by malnutrition.

Most crack smokers are poor, very few eat well, and nearly all of them smoke. Smoking causes damage to the fetus that is much easier to demonstrate than the theoretical damage caused by cocaine. The media are filled with the cocaine-baby issue. "Have you ever seen a cocaine baby?" But do we hear them asking "Have you ever seen a baby born to a smoker?" Or, "have you seen the babies of malnourished women?"

To pretend that any effects produced in pregnant rats, by a dose of cocaine which is many times larger on a weight basis than the supposedly lethal human dose, are relevant to public health, is crude propaganda, and presumably has the purpose of supporting political, judicial or military actions that are completely unrelated to public health or morality.

Putting the medico-legal propaganda in its best light, it is scientifically atrocious. But the actual moral issue is that it is not used for any constructive purpose. One nutritious high protein meal every day would probably solve the "cocaine baby problem," but it appears that neither the government nor the medical establishment is interested in solving the problem.

Novocaine (procaine) was introduced as a substitute for cocaine, but it has been found to have protective effects on the organism, as an adaptogen. Lidocaine and other local anesthetics have many important protective effects. In this context, some experiments that hint at a fetus-*protecting* effect of cocaine deserve further investigation.

Cocaine was displaced from medical use, first by the proprietary synthetic local anesthetics, and then, in the 1930s, by the proprietary amphetamines.

As a stimulant, cocaine increases the metabolic rate, which in turn can lead to the wastage of protein, to provide energy. Conventional first aid for a cocaine overdose includes providing glucose and thiamine, to provide energy. The same nutritional support, but preferably with additional protein, is obviously appropriate for protection of the fetus. The presence of increased amounts of ammonia in the urine indicates malnutrition in both adults and newborns, and might be a useful indicator for nutritionally stressed pregnancies. Supplementing both dietary protein and carbohydrate might be the simplest treatment for many types of gestational stress, including preeclampsia and "recreational" cocaine use.

The Andean people who use coca regularly appear to suffer no harmful effects. Coca chewing prevents the hypoglycemia that can be produced by extremely high altitude. It is common to keep a wad of the leaf in the mouth all day. The dental health of coca-chewers is so good that a Bolivian company has marketed a toothpaste containing coca leaf. (But it is probably the high altitude itself that is mainly responsible for their good teeth.) The coca leaf has been used medicinally in South America for improved fertility, prolongation of virility into old age, prevention of altitude sickness, and various other purposes. The association of coca chewing in these cultures with magic and gods with erect phalluses (*El Tio, Supay*) probably affected the herb's treatment by the anti-erotic cultures.

At very high altitude, fertility is limited by the availability of oxygen. Altitude itself tends to increase the ratio of progesterone to estrogen, as a protective adaptation involving increased carbon dioxide in the tissues. Cocaine increases the production of the pituitary gonadotrophin, LH

(luteinizing hormone), which increases ovarian progesterone production. In men, LH increases testosterone production. Chewing coca leaves has been found to sharply increase the amount of progesterone in saliva. Increased progesterone would increase the ability to maintain pregnancy under stressful conditions.

Used moderately, for health purposes, there would seem to be no problem with cocaine, and there seems to be a physiological rationale even for its use during pregnancy under some conditions. The use of progesterone, thyroid, and nutrition would obviously be better ways to protect fetal development.

Smoking during pregnancy is a much bigger public health issue than cocaine use. Ranking with smoking, in terms of damage done to developing babies, are prescribed diuretics, inappropriate drugs for epilepsy during pregnancy, weight-control diets for pregnant women, x-rays of the developing fetus, and--probably the biggest problem of all--poverty and malnutrition.

"The evidence provided by Spear and colleagues (1989a, 1989b), however, indicates that this deficit is relatively transitory and is not found in animals after perhaps 15 days . . . . " "The available evidence would appear to indicate that significant, biologically meaningful deficits on these tasks are not found over a wide range of doses. There are a number of reasons for these failures to find effects."

Acta Obstet Gynecol Scand 1979;58(1):37-40. **Perinatal death due to abruptio placentae in an African city.** Naeye RL, Tafari N, Marboe CC Abruptio placentae was a common cause of perinatal death in Addis Ababa, Ethiopia in 1974-1975 with a frequency of 5.5/1000 births. This disorder had its peak frequency at term. No abnormalities were found in the placentas to explain the placental abruptions but there were other clues to their genesis. There was **a strong association of the fatal abruptions with severe poverty in the mothers. These poor mothers were both undernourished and malnourished during pregnancy.** Their fetuses and neonates who died had multiple evidences of undernutrition including a relative undergrowth of adrenals, spleens and livers and a relative acceleration of lung maturation. These findings support observations in more prosperous nations that poor nutrition of the gravida may have an important role in the genesis of abruptio placentae.

S Afr Med J 1988 Jul 16;74(2):53-4. **Influence of perinatal care on stillbirths in patients of low socio-economic class.** de Jong G, Pattinson RC, Odendaal HJ. In a series of 12,587 deliveries in patients of low socio-economic class, there were 356 stillbirths; prospective analysis of these showed that 42.1% occurred in the 4.7% of cases in which the mother had received no antenatal care. When booked and unbooked patients were compared it was found that the rate of stillbirths due to infection and anoxia was significantly higher among unbooked patients, who also accounted for more intra-uterine deaths due to abruptio **placentae and congenital abnormalities. We speculate that diet and nutrition might play a major part in the causation of these intra-uterine deaths.**

PREMISES FOR AN ARGUMENT:

Environmental factors, including polyunsaturated fats, exogenous estrogens, and heavy metals, and nutritional deficiencies, create an exaggerated estrogenic state, which synergizes with other intermittent stresses. These external stressors provoke the release of many kinds of stress mediating signal substances.

Aging is a progressive inflammatory state, in which there is an imbalance between excitatory and restorative processes, that progresses toward a shock-like state.

The antistress hormone, cortisol, causes tissue atrophy and cellular death in the process of resisting chronic stress.

Circulation and metabolism influence each other, with inflammation and shock, hypoxic metabolism and hypoperfusion promoting each other.

Inflammatory mediators damage mitochondrial respiration and cause cell swelling. Swelling impairs circulation and cell function.

Inflammatory autoimmune diseases and diabetes are much more common in women than in men. Insulin resistance appears at puberty, and diabetes is more common in girls than in boys. At menopause, 50% of women have distinct insulin resistance. Insulin resistance and the inflammatory autoimmune diseases are clearly promoted by estrogen.

The chronic increase of cortisol in response to stress increases estrogen.

Changing metabolism, producing lactate rather than carbon dioxide, changes the pH of the cell and its water content, allowing water-soluble metals to enter mitochondria.

Diabetes, neuropathies, myopathies, schizophrenias, the degenerative brain diseases, congestive heart failure, multiple organ failure, reduced lung function, insomnia, nocturnal cramps, and many other disorders have similar metabolic features, justifying similar therapies.

Estrogen, calcium, heavy metals, and nerve degeneration.

In the 1960s, someone noticed that a certain crease on the ear-lobe was a strong indicator of the tendency to have a heart attack. A little later, different researchers showed an association of wrinkled skin with smoking, and a strong association between the percentage of polyunsaturated oils in the diet and premature wrinkling. At the same time, people were demonstrating that many factors contributed to the stiffening of connective tissues, and to a generalized "fibrosis." Intuitively, everyone seems to know that the state of the skin is an indicator of general vitality or decrepitude. But the habit of thinking in terms of specific diseases, rather than general processes, has kept people from seeing that wrinkles, and other connective tissue changes, are deeply related to the major diseases of aging.

The senile brain accumulates a variety of mineral deposits, and the argument has been made that dietary aluminum is the cause of Alzheimer's disease. It would be good to eliminate added aluminum from our public water systems and from our foods, but there is good evidence that other processes are behind the accumulation of aluminum and other minerals in our tissues.

With aging, minerals such as calcium, iron, aluminum, cadmium, lead, mercury, fluoride, uranium, etc., accumulate in animal tissues, especially when those tissues are metabolically defective. But as the soft tissues mineralize, the bones and teeth demineralize. In both hard and soft tissues, mitochondria regulate mineralization.

Mercury has been used medically for a long time, and one of the popular uses for mercurial compounds has been as a diuretic. The mercurial

diuretics suppress the kidneys' respiratory activity and their ability to retain minerals, allowing fluids to pass through them relatively unconstrained. This led to the understanding that the mercury acted by interfering with the sulfhydryl groups (mostly the cysteines in proteins) in kidney cells, so when microscopic studies showed that the mercurial diuretic caused calcification, beginning in the mitochondria, this added to knowledge of how mitochondria work, as well as to the general process of soft tissue mineralization.

Hans Selye studied the process of metal-induced calcification in rats. In one group of experiments, he showed that an excess of iron causes calcification of areas of skin that have been slightly injured, for example by having the hair plucked. Treatment of the rats with vitamin E blocked the oxidative effects of iron and prevented calcification. Ordinary injuries, such as bruises, sometimes calcify, presumably under the influence of hemoglobin and iron.

Many toxins that oxidize the sulfhydryl (SH) groups in mitochondria synergize with calcium overload to produce metabolic inactivation of the mitochondria, usually accompanied by swelling. For many years it has been recognized that a practically instantaneous effect of estrogen is to cause cells to take up water. Its next step is to stimulate the synthesis of fats. Both of these processes involve pervasive changes in the energetic processes of the cells. Among the later changes produced by estrogen is increased collagen production.

It has long been recognized that injury or irritation is likely to lead to calcification, through the stages of inflammation, edema, and fibrosis, sometimes with fatty degeneration. These are the changes that led people to think of radiation damage as a form of accelerated aging. X-ray treatment commonly causes calcification of important organs such as the brain and the heart, though skin calcification was among the first radiation side-effects noticed. After 100 years of relative scientific inertia, there has recently been some progress in understanding the common processes behind "injury induced mineralization."

The biochemical arguments in the next few paragraphs simply outline some of the facts that have been omitted from the mainstream discussions of brain aging, estrogen, and mineralization.

When I began studying the physiology of estrogen, I found that the biochemical changes it caused were the same as those of aging, oxygen-deprivation, and radiation injury.

In my experiments, I found that both aging and estrogen stimulation caused a great increase in the availability of reactive electrons, which I measured by their reaction with a dye. These electrons come from an interactive system that involves the proteins (cysteine) and glutathione, and the various cofactor-catalysts such as ascorbic acid and NADH (NAD is nicotinamide adenine dinucleotide; the name reveals its connections to the vitamin, niacin/nicotinamide, and to the "energy molecule," ATP, adenosine triphosphate, but biochemists are seldom concerned with those links; the H indicates the reduced, electronically energized form of the molecule).

Glutathione and other antioxidants tend to prevent oxidative damage to the mitochondria's sulfhydryl groups. Simply lowering the pH is highly protective against oxidative attack by metals, and this is partly because the electrons of the sulfhydryl groups are less accessible to the oxidants in an acidic environment. The formation of carbon dioxide is the fundamental process for keeping mitochondrial pH low.

Glutathione depends on being regenerated by the reducing molecule, NADH. When NADH is consumed elsewhere at a high rate, glutathione itself becomes oxidized and unable to protect the mitochondria, and the consumption of NADH (as in the formation of lactic acid) tends to consume protons, raising the pH. So the rate at which NADH is consumed can be crucial in the life and health of a cell. NAD is so closely related to the availability of ATP that the cell death system can be triggered by a deficiency of NAD (Catisti, et al., 1999).

The cell's reductive system, centering on NADH and NADPH (the extra P, phosphate, in this molecule allows it to be regulated separately from NAD), is closely involved in fat synthesis. If estrogen serves as a redox (reduction and oxidation) link between NADH and NADP, fat

synthesis will be an additional drain on the available NADH.

In the 1950s, several endocrinologists gathered evidence to show that estrogen can function as a catalyst in the oxidation and reduction of the pyridine nucleotides, NADPH and NADH. But in the 1960s, the doctrine that estrogen's effects were mediated exclusively by the "estrogen receptor" began replacing all other ideas about estrogen chemistry and physiology.

J. G. Liehr, and a few others, are still demonstrating that estrogen can function as a catalyst in "redox cycling" (alternate reduction and oxidation), which generates toxic free radicals, and can potentially serve as a drain on the NADH systems. In functioning as a redox catalyst, estrogen oscillates between an oxidized and a reduced molecular form. In this context, the ratio of the different forms of estrogen takes on an entirely different meaning than simply their different effects on the so-called estrogen receptors. Since the doctrine of the estrogen receptor became a medical preoccupation, most attention has been given to estradiol, since it is the "strongest" estrogen in some tests, though estrone, the oxidized form, is usually present in the blood in much larger quantities. The quantity of the oxidized form of estrogen is increased in certain degenerative conditions, such as uterine cancer, which is a strong argument against the idea that, as a "weaker estrogen," it would moderate the effect of estradiol.

In my dissertation, I gave a few other arguments regarding the wasteful consumption of NADH. There is now good evidence for the existence of estrogen-stimulated extramitochondrial NADH oxidases, in addition to the NADH oxidase function of age pigment, that I have discussed in an earlier newsletter.

Until the late 1970s, the fact that estrogen causes increased absorption of calcium was offered as proof that it prevents osteoporosis, but then it turned out that the increased retention of calcium was occurring ***only in the soft tissues,*** where calcification is a normal trend with aging. In fact, bone loss begins in a woman's twenties, and continues fairly steadily during the period in which the actual level of estrogen is rising.

Arteries and tendons tend to calcify with aging, the brain and pineal gland, kidneys and other organs retain more calcium and gradually lose functions, and cells die with a calcium overload.

Estrogen's stimulation of iron absorption was ignored by people who wanted to sell iron pills (often 18 mg per day) to women who lost iron (maybe 5 mg per month) by menstruation. After menopause, women absorb iron so fast that their body's iron load generally catches up with men's within a few years, at which time their incidence of heart attacks becomes similar to men's. If estrogen is a major factor in the promotion of iron absorption, **women's accelerated iron retention after menopause argues for the existence of a *more estrogenic state than when they were younger.*** Since progesterone falls sharply at menopause, the effect of the unopposed estrogen is going to be very strong, even as the absolute quantities of estrogen are declining.

When progesterone falls, the effects of cortisol, as well as estrogen, are increased, because progesterone antagonizes both of those hormones. Under the influence of cortisol, fat cells produce estrogen, and this effect is normally inhibited by progesterone and thyroid.

Calcification of soft tissues and iron retention accelerate at menopause. The body accumulates calcium, but it isn't going into the bones. The body accumulates iron, and it too goes into the soft tissues. Increased iron storage in the liver is associated with insulin resistance, and increased iron in any tissue is associated with increased lipid peroxidation in stress.

Calcium and iron tend to be deposited together, and the mitochondria are usually the starting points for their deposition. Iron overload has been implicated in heart disease, cancer, diabetes, and many other degenerative diseases, including the brain diseases.

Estrogen, and the free fatty acids that are liberated under its influence, increase the permeability of blood vessels, allowing water, proteins, etc., to leak out into the tissues. Tumor necrosis factor, induced by estrogen, reduces the "blood

brain barrier" function, promoting brain inflammation. The "blood brain barrier" means that water soluble molecules are excluded, while oil soluble molecules enter freely. Highly charged particles such as metal ions are normally efficiently excluded from the brain, in proportion to their water-solubility..

The free unsaturated fatty acids associated with estrogen's influence cause brain edema and mitochondrial damage (Catisti, et al., 1999). Although the fatty acids enter cells and mitochondria easily because the cytoplasm and mitochondria are lipophilic, unsaturation of a fat makes it a little less fat soluble, and more water soluble. Unsaturation also makes the fat more likely to be oxidized into toxic products, and to damage the mitochondria, suppressing its respiration, and forcing the cell into the less efficient glycolytic metabolism, raising the cell's pH, which makes the cell take up more water.

All of the biochemical features of Alzheimer's disease are consistent with prolonged estrogen excess. Estrogen's toxicity to the developing brain was established in the 1950s and 1960s. Maybe it's a kind of progress, that the claimed benefits of estrogen have aged with the drug industry: in 1940 estrogen helped you get pregnant, in 1950 it helped you to maintain pregnancy, in 1960 it helped to prevent or interrupt pregnancy, in 1970 it helped you retain calcium and iron to build strong bones and blood, in 1960 and 1990 it helped prevent heart attacks, and now finally it has nothing left to do but to prevent senile dementia.

The virologist, Gajdusek, wanted to argue that his virus, and not the accumulation of aluminum, was responsible for kuru and other brain degenerative diseases, and so he did a survey of brains of demented people from regions with different types of soil, and showed that the most abundant metals in the environment showed up in the brains. He argued that this showed that the metal deposition was just the consequence of a viral disease, rather than the cause of the brain degeneration. He observed that the deposits consisted mainly of calcium in regions that didn't have large amounts of other metals, so he argued that a particular metal such as aluminum couldn't be responsible for brain degeneration. But he didn't consider that factors other than viruses might be responsible for the brain mineralization that he saw.

Although women have more osteoporosis and more Alzheimer's disease than men do, the *lack* of estrogen is currently blamed for both of the problems. Why would Alzheimer's disease be so different from the other predominantly female diseases that have been linked to excess estrogen? Why would women's brains be different from men's? Why would their nerve cells degenerate without estrogen, while men's don't? Obviously women's brains and nerves aren't very different from men's and there simply isn't any sensible reason to believe that "estrogen deficiency" is responsible for Alzheimer's disease, or for osteoporosis, or for heart disease, or any of the other problems that have been blamed on the "menopausal estrogen deficiency."

The mass media find and publicize the things they want to believe, or want the public to believe. "Coffee causes heart disease," "estrogen prevents Alzheimer's disease," they say. How do they make the argument? Using plausible sounding terms that hide the real situation is the general technique. I don't want to give science reporters disproportionate blame, because specious argumentation is habitually practiced by many of the professors and researchers who provide the raw material for the news reports. In literature, "poetic diction" is intended to put the reader into a certain frame of mind, to be receptive to the poet's purpose. Many scientists rely on something like "poetic diction."

For example, a San Francisco study by Kristine Yaffe and co-authors found that "free estrogen," "the active form of the hormone," was higher in more of the people who had better cognitive function. Yaffe, et al., also found that dementia is associated with both depression and osteoporosis.

There isn't really such a thing as "free estrogen," which is defined in terms of a particular laboratory situation that doesn't correspond to anything in the body. Estrogen is insoluble in water, unless there is a large amount of alcohol present as solvent. When solids are present in a solution, estrogen passes directly from one solid to another, according to the momentary properties

of the solids. The laboratory measurement of "free estrogen" is describing both a physiological and a physical fantasy.

"Protein bound estrogen" is an active form of estrogen, and the estrogen bound to albumin probably accounts for most of estrogen's activity. Free fatty acids, which compete with estrogen for binding to the steroid-binding globulin, probably modify the properties of the more abundant albumin so that it binds more estrogen in its active form, causing estrogen to move from other proteins, lipoproteins, and red blood cells onto the activated albumin. **The presence of fats bound to the albumin makes the albumin more lipophilic, fat-loving, and molecules are taken up into cells--especially brain cells--according to their solubility in fats. For fatty molecules, there is no "blood brain barrier."** The fact that albumin has variable lipophilicity makes it an effective mechanism for the transport and delivery of oil soluble molecules.

Yaffe, et al., in associating depression and osteoporosis with dementia, are arguing that estrogen deficiency is the cause of all three conditions. They offer some hypothetical mechanisms for how estrogen might prevent Alzheimer's disease. Observing that brain cells die in people with Alzheimer's disease, they mention that estrogen stimulates "dendritic sprouting" in brain cells, as if that could compensate for the loss of cells (it doesn't). They observe that estrogen delivers more tryptophan to the brain, increasing the production of serotonin, and that it inhibits the monoamine oxidases and other enzymes that inactivate transmitter substances, increasing the activity of adrenaline, serotonin, and other transmitter substances. They suggest that increased circulation caused by estrogen might protect the brain. Here, Yaffe, et al., have invoked **the serotonin myth and other myths, including the nitric oxide myth, to substantiate the estrogen myth.**

Serotonin doesn't "cure depression," and both serotonin and nitric oxide impair circulation and are toxic to brain cells. Both of them poison mitochondrial respiration. Estrogen increases the viscosity of blood, and impairs circulation and oxygenation in many other ways.

The actual level of estrogen rises all through the reproductive years, and at menopause, the reduction in antiestrogenic factors, such as progesterone, thyroid, and DHEA, leads to increased effects of estrogen. The increased burden of unsaturated fatty acids that accumulate with aging clearly promotes the effects of estrogen and interferes with the production of the antiestrogenic hormones. These unsaturated fats cause progressive slowing of the metabolic rate, with particularly sharp decreases around puberty and menopause. As they interfere with the production of energy, they tend to increase cellular energy requirements, by promoting excitatory cellular processes.

Estrogen and PUFA create insulin resistance, and the resulting state of "diabetes" and stress de-energizes tissues, with the mitochondria that are damaged by unsaturated fatty acids, nitric oxide, tumor necrosis factor (TNT), serotonin, etc., failing to meet the tissues' energy needs. Stress, endotoxinemia, and increased estrogen tend to activate TNF, which has a role in brain degenerative diseases and osteoporosis and multiple organ failure. Much research has focussed on a search for a single substance that is responsible for the inflammatory conditions of Alzheimer's disease, but inflammation and aging are processes that involve many causes and mediators, with each individual's history causing variations in the details.

"Diabetes," or the inability to oxidize glucose vigorously, is simply a description of the metabolic aspect of cellular degeneration. The neurological impairment that is so commonly associated with officially diagnosed diabetes is simply one aspect of a general cellular malfunction that follows from chronic energy deprivation. Exactly the same processes occur in the sudden organ failure produced by shock, or the gradual organ failures--lungs, liver, kidney, heart, thymus, brain--that occur in aging. In general, there is a failure of circulation that exacerbates the metabolic and functional failures.

Diabetes, of both the insulin dependent and the non-insulin dependent types, is commonly associated with increased cortisol. In diabetes, inflammatory conditions, and under the influence

of increased cortisol, brain cells are deprived of glucose.

Increased cortisol is a normal response to the cell-damaging effects of stress or inflammation, but cortisol itself causes the death of nerve cells and immune cells through excitotoxicity, by blocking glucose metabolism. Estrogen increases cortisol production in a variety of ways, acting both through the pituitary and directly on the adrenal glands. Estrogen promotes excitotoxic processes, by opposing progesterone and thyroid, by directly exciting nerve cells, and by increasing the activity of excitatory nerve transmitters. It also increases serotonin, which blocks energy production by its effect on mitochondria, as well as by impairing circulation..

At puberty, there is a sudden increase in the incidence of depression, especially in girls. Increased adrenaline, like increased cortisol, is a feature of depression, stress, and inflammation; mobilizing fats, it can become part of a vicious circle, in which free fatty acids cause insulin resistance, activating the stress reactions. Increased serotonin is a feature of inflammation, shock, stress, and depression, and, like histamine, is tied very closely to estrogen's effects.

Estrogen does have some of the effects mention by Yaffe, et al., but these effects should make a person wonder whether estrogen isn't an important factor in the development of Alzheimer's disease, rather than being its main preventive agent.

In Alzheimer's disease, there is a distinct decrease in blood pressure, and orthostatic hypotension is a common feature of dementia. Estrogen's relaxing effect on the blood vessels has been shown to allow blood pooling in the veins, producing orthostatic hypotension. Estrogen, acting directly and through mediators such as serotonin, decreases the heart's pumping efficiency.

Blood viscosity is increased in Alzheimer's disease, and estrogen is known to increase blood viscosity.

Nitric oxide, a third cultic substance along with serotonin and estrogen, is invoked as a normalizer of brain circulation and protector of nerve cells from peroxidation. Whether a substance is an antioxidant or pro-oxidant depends on its environment, and both nitric oxide and estrogen are pro-oxidants, promoters of lipid peroxidation and other forms of cell damage, under a variety of physiological situations.

If authors are criticizing a well known doctrine, it is reasonable for them to assume that their readers know the arguments in favor of that doctrine, and to concentrate on their critical points. But Yaffe, et al., are arguing *in favor* of a well known doctrine. They fail to present the actual research situation. For them to ignore the work of people like Brawer, Desjardins, Schipper, and Liehr, who have explored the cytotoxic and neurotoxic effects of estrogen, amounts to simple propaganda. When such material is published in the mass media, such as JAMA, its effect can be considered as equivalent to fraud, since these media don't publicize alternative views.

While there has been some publicity about a recent study that found that treating Alzheimer's patients with estrogen for 12 weeks didn't improve their mood or mental ability, there has been relative silence about all the studies that show actual deterioration of mentality or mood in association with increased estrogen.

In old men, higher estrogen was found to be associated with lower mental ability (Barret-Connor, et al., 1999). Although estradiol is the most potent estrogen, estrone is the main estrogen in the circulation in terms of its quantity, and women's mental performance was found to be lower when the estrone was higher (Yaffe, et al., 1998).

Antiendorphin, antiexcitotoxic, anticholinergic, antiserotonergic, antiprostaglandin, and antiglucocorticoid drugs have been used with good effect in various degenerative nervous diseases, but all the so-called "anti" drugs are imprecise antagonists, and have many side effects. The natural antagonists and nutrients are usually helpful. Protein, sodium, magnesium, carbon dioxide/bicarbonate, progesterone, thyroid, vitamins, etc., can be curative in many brain diseases, but are seldom tried because of cultic medical ideas about nutrition, hormone tests, and the nature of cells and disease.

To the extent that unsaturated fats, heavy metals, and estrogenic substances (such as soybean products; tofu, for example, was recently implicated in dementia) can be avoided, the interactive processes of cell damage can be retarded. Natural restorative processes can maintain tissue integrity if the destructive processes are slowed.

"Estrogen **withdrawal induced a significant increase in the nucleoside triphosphate:Pi ratio in the two estrogen-dependent xenografts, whereas this ratio remained** unchanged in the estrogen-independent tumors." [Tumor growth was inhibited, and the ATP increased.]

Carcinogenesis 1998 Jul; 19(7):1285-90. **Enhancement of estrogen-induced renal tumorigenesis in hamsters by dietary iron.** Wyllie S, Liehr JG. Iron participates in the generation of hydroxyl radicals by the iron-catalyzed Fenton reaction. Its role in estrogen-induced carcinogenesis has been examined in this study by investigating the effects of iron content of hamster diets on tumor induction by estradiol. The renal tumor incidence and number of tumor nodules in hamsters treated with estradiol plus a diet enriched with iron (384 p.p.m. Fe as ferric citrate) for 5 months were 2- and 4-fold higher, respectively, than those observed in animals on an iron-poor diet plus estradiol (3.9 p.p.m. Fe, as ferric citrate). Tumor incidence and number of tumor nodules in estradiol-treated hamsters on the iron-deficient diet were not different from those of animals on a normal rodent chow. No tumors were detected in hamsters treated only with the low or high iron diets. Total serum iron was significantly increased in animals treated with the high iron diet plus estradiol compared with the low iron diet plus estradiol group and the high and low iron controls. Estrogen treatment increased non-heme iron in liver of both high and low iron treatment groups and in kidney of the hamsters on the low iron diet. It is concluded that dietary iron enrichment enhances the incidence and severity of estrogen-induced tumor induction.

Annu Rev Nutr 1997;17:37-50. **Toxic and essential metal interactions.** Goyer RA. Cadmium, lead, mercury, and aluminum are toxic metals that may interact metabolically with nutritionally essential metals. Iron deficiency increases absorption of cadmium, lead, and aluminum. Lead interacts with calcium in the nervous system to impair cognitive development. Cadmium and aluminum interact with calcium in the skeletal system to produce osteodystrophies. Lead replaces zinc on heme enzymes and cadmium replaces zinc on metallothionein. Selenium protects from mercury and methylmercury toxicity. Aluminum interacts with calcium in bone and kidneys, resulting in aluminum osteodystrophy. **Calcium deficiency along with low dietary magnesium may contribute to aluminum-induced degenerative nervous disease.**

Mech Ageing Dev 1998 May 1;102(1):1-13. **Iron accumulation in aging: modulation by dietary restriction.** Cook CI, Yu BP. "Male Fischer 344 rats fed ad libitum or dietary restricted (maintained on 60% of ad libitum food intake) were sacrificed at 6, 12 and 24 months of age." "Tissue total iron content was shown to increase significantly with age in animals fed ad libitum (AL). At 24 months, these animals showed comparable iron content increases in the liver and kidney, but were significantly greater than measurements found in brain. This age-related iron accumulation, however, was found to be markedly suppressed by dietary restriction (DR) in all tissues. Similarly, LPO measurements increased in an age-related, tissue-specific fashion. **At 24 months of age, measurements of LPO in AL rats brain and liver exceeded measurements in kidney. Again, we found DR to markedly suppress age-related LPO in all tissues.** Reported here are our findings on the ability of DR to modulate iron status at the tissue level. Consistent with the proposed anti-oxidative mechanism of DR, these findings further suggest that the modulation of tissue total iron content is an important component of that mechanism.

Fibrosis is an outstanding feature of aging: Skin, joints, liver, kidneys, heart and blood vessels, even the brain, undergo fibrotic changes in association with disease, injury, and aging.

Excitotoxins are fibrogenic

Estrogen is excitotoxic and fibrogenic

Lactate is fibrogenic

Edema precedes fibrosis

Injury and inflammation are fibrogenic

Free radical peroxidation is a common pathway leading to fibrosis, as in cirrhosis of the liver in which unsaturated fats and free radicals have central roles.

Saturated fats, antihistamines, thyroid hormone, and other antiinflammatory agents prevent or reverse fibrosis.

The fibrous extracellular material regulates specialized cellular functioning, and is a protective buffer.

Fibrogenesis commonly precedes carcinogenesis.

Cancerization is a "field process," not primarily a unique "genetic event."

Proteolytic enzymes continuously dissolve and remodel the extracellular matrix.

Unsaturated fats inhibit proteolytic enzymes.

The resistance of the fibrin in blood clots to enzymic dissolution is increased by unsaturated fats.

Antifibromatogenic hormones oppose the development of the fibromas and cancers that are caused by estrogen.

The first principle in reversal is to stop the pathogenic process, and to stop the stress- induced cell death. Then restorative processes can come into balance with degenerative.

FIBROSIS: Estrogen, stiffness, excitotoxicity, aging--a problem more general than "collagen disease"

Thirty years ago, my professors said that any publication more than ten years old wasn't worth reading; that was apparently why I never saw the professors in the library. In a span of ten years, a change of 45 degrees in scientific orientation is thought to be progress. But in 40 years, those changes of orientation can produce a turn of 180 degrees, in which things that once seemed to be firmly established and full of potential have simply been removed from the academic canon. The biology of fibrosis is one of those important things that came to be neglected even while massive amounts of new evidence were confirming the old views.

At the beginning of the 20th century, Eli Metchnikov argued that changes in the connective tissues were the cause of aging. He also argued that intestinal toxins were important causes of the aging changes.

Early in the century, x-rays were found to produce tissue burns. The early effect of a radiation burn is inflammation and edema. The edema gradually gives way to fibrosis, and if the person lives long enough, the fibrotic tissue may calcify.

In the 1930s, Leo Loeb found that large doses of estrogen stimulated massive synthesis of collagen in the uterus.and vagina, and noticed that these effects resembled the increased accumulation of collagen that occurs with aging. In the 1940s, Alexander Lipshutz showed that very small, but continuous, doses of estrogen caused fibromas to develop in many tissues besides the uterus, and that these fibromas tended to develop

into cancers. Later, estrogen was found to accelerate the stiffening of the collagenous tissues that normally occurs with aging.

In the 1930s, the Shutes, father and sons, found that the clotting-associated diseases of pregnancy were prevented by vitamin E, and they proposed that vitamin E acts as an antiestrogen, protecting against the increased clotting problems caused by excessive estrogen. They showed that vitamin E activates the proteolytic, fibrinolytic, enzymes that remove blood clots.

Conventional beliefs identified vitamin E as an antioxidant that prevented oxidation of unsaturated fats, and this function of vitamin E appeared to make it inconceivable that vitamin E could also be of value in relation to the circulatory system. This attitude was still dominant in the 1970s among dietitians, physicians, and university professors. Besides ignoring or ridiculing the Shutes' work, mainstream journals would occasionally publish papers denying that vitamin E facilitates clot removal, or that estrogen promotes clotting, attempting to defend their 180 degree turn.

Just after the turn of the century, unsaturated fats were found to inhibit proteolytic enzymes. Repeatedly, the presence of unsaturated fatty acids has been shown to impair clot removal, either by its effect on proteolytic enzymes, or by being incorporated into the clot and making it resistant to dissolution.

Fibrin, the material that forms blood clots, is always in the process of formation and dissolution, in a kind of equilibrium. A thin layer of it coats the outside of blood cells, and the inside of blood vessels. When capillaries are leaky, some of the fibrin and its depolymerized subunits, leak out into the tissues. There is a complex interaction between fibrin and collagen, in which fibrin stimulates the formation of collagen (AJ Gray, et al., 1995) and collagen stimulates the fibrin clotting process.* Fibrin clots stimulate the growth of fibroblasts, and leaky blood vessels (Brown, et al., 1989) can lead to tissue fibrosis, though there are routes to fibrosis that don't involve fibrin.

Blood vessels leak under the influence of estrogen, irradiation, oxygen deprivation, vitamin E deficiency, free fatty acids, lactic acid, and various stress mediators, such as histamine and serotonin; particles as large as red blood cells can pass right through the endothelial cells. The loss of the blood vessels' ability to serve as a barrier corresponds to a disturbance in the structure of the cells, and this structural permeability is apparently the result of an imbalance in the state of the electrons in the proteins, the redox (reduction and oxidation) state, regulated by glutathione and other antioxidants and energy regulators.

The internal state of any cell, not just in the blood vessels, is governed in similar ways by cellular energy and the redox state of proteins, and in the oxidatively disturbed state, cells take up water, as well as being abnormally "permeable" in both directions. For example, when a cell is deficient in vitamin E it loses molecules such as ATP and proteins, that diffuse out into the extracellular spaces. When cells are in an energy deficient state, as in hypothyroidism, they are in this leaky, edematous state.

This state of near exhaustion is similar to the "excitotoxic" state that's caused by an imbalance between stimulation and energy production. In the brain, excitotoxins have been found to produce a kind of fibrosis, in which the cells that normally produce the myelin sheath surrounding nerve axons begin producing collagen, and appear to change into a type of cell (Schwann cell) that is not normally found in the brain. **The production of collagen seems to be a very basic kind of defensive reaction to excessive stimulation or oxygen deprivation.** This makes it possible to see "excitotoxicity" as a general process, that includes the kind of fibrosis and calcification of skin that Hans Selye produced (by combining vitamin E deficiency with heavy metal toxicity and local

---

**In the 1920s, W. F. Koch was proposing that oxidative free-radical processes governed the clotting of blood, the healing of wounds, and possibly the calcification of devitalized tissues. At that time, free radicals were an esoteric matter of interest mainly to a few polymer chemists, and it was considered absurd to suggest that cellular respiration could relate to extracellular fibrous matter.*

irritation), as well as the aging of brain cells produced by prolonged estrogenic stimulation. Scleroderma, like the other "collagen diseaes," affects women (during their reproductive years) much more often than men. Retroperitoneal fibrosis, which can seriously damage the kidneys and other abdominal organs, has been compared to uterine fibroid tumors, and it is commonly treated successfully with the antiestrogenic drug, tamoxifen. Tamoxifen has also been used to treat keloids and to prevent abnormal scars in plastic surgery. (I have seen keloids regress quickly following the application of vitamin E with antiestrogenic hormones.) The fibrotic response to the excitotoxic imbalance can be seen in practically all chronic and degenerative diseases.

Fibrosis is an abnormal progression of the normal formation of fibrous material between cells, and it usually involves an increase in the volume of the extracellular material, and an increase in the percentage of collagen in that matrix, and an increased rigidity of the collagen that results from chemical cross-links, that are analogous to the polymerization of a plastic, or the vulcanizing of rubber. Arteriosclerosis is probably the best known medical example of tissue fibrosis, but it's the same phenomenon that makes the meat from an old animal tough and rubbery.

Although "stiffness" is a familiar term in engineering and biology, it has some different meanings in different situations. When a tissue swells up with water until it's tight, it is stiffer than in its natural condition. The material of tendons and ligaments gets stiffer by increasing its density and toughness. When a bone gets old, it gets brittle and weak, and in one sense it is stiffer than a child's bone, since a child's bone can be deformed without breaking. While the engineering definitions can't be applied to all tissues in a simple way, biologically it's useful to think of stiffness as something that progresses along with fibrosis, as the function of a tissue decreases. In the first stage of tissue injury, swelling stiffens a tissue; after prolonged edema, there may be an increased volume and concentration of collagen around cells; finally, the density of the collagen can increase, and can calcifiy, as in the sclera of the eye, the arteries, heart valves, pericardium, and even the heart muscle itself.

In diseases of stress and aging, there is a general inflammatory state, that can end in multiple organ failure. Congestive heart failure illustrates some of the effects of this energy-poor, inflamed and edematous state: The heart's function is reduced because of stiffness caused by increased water and calcium in the cells; at the same time, arteries are stiff and resistant, impairing the flow of blood and making regulation of blood pressure difficult. In chronic hypothyroidism, the heart gradually becomes fibrotic, and this provides an opportunity for calcification to occur.

If a callus is a metaphor for the normal, protective function of connective tissue, then a corn is a metaphor for the harmful overdevelopment of the protective reaction. The ordinary minor mechanical tensions and pressures that occur in any living animal, as well as the biochemical gradients produced by metabolizing cells, shape the connective tissues that keep cells in their particular place in the organism. When gelatin, made by boiling connective tissues in water, is injected into a growing organism, the randomly arranged molecules of the melted collagen can be seen to organize themselves back into the coherently aligned cable-like structures of normal connective tissue.

Cells decide what they will be and do according to their surroundings. Normally, cells live in contact with a layer of non-cellular material containing fibrous and elastic and gelatinous material, that functions as a medium of communication with other cells. Irritation, stress, and shock commonly produce a series of tissue reactions, including edema, fibrosis, calcification, and death, but with certain possible alternatives, such as a return to the normal state, or early cell death, or lipodystrophy (fatty degeneration), or tumefaction (development into a tumor).

Although there are specialized cells, fibroblasts, that form large amounts of connective tissue, they are very closely related to muscle cells, fat cells, and glial cells, and the functions of one can sometimes change into those of another type. One of the main problems of biology in the

last century has been to understand the factors that cause one kind of cell to change into another. One of the functions of the collagen layer secreted around cells appears to be to provide a degree of insulation from the numerous "inductive" factors, so that a cell can remain what it is.

Conditions in the whole organism affect the way an individual cell will relate to its immediate environment. Nutritional deficiencies or imbalances will make special demands on certain types of tissue. Increased collagen production can provide some protection against toxins, but the protective layer also limits the cells' access to the blood supply.

Cells in their excited and exhausted state are increasingly open to penetration of the toxins, because of their own increased permeability, and because of the increased leakiness of the blood vessels. Certain environmental toxins accumulate more rapidly as the cells lose their ability to destroy them. Several kinds of toxin, including the unsaturated fats, inhibit the proteolytic enzymes that remodel tissue, and reduce the ability to dismantle and rebuild the extracellular matrix.

Collagen is a very unusual protein, since it lacks tryptophan and cysteine, and contains a very high percentage of glycine. Glycine is the simplest amino acid, and serves as an inhibitory transmitter. It has some remarkable protective activities against toxins, but even the process of forming it has some uniquely protective consequences: It is made from sugar, with the addition of ammonia removed from glutamic acid, leaving ketoglutaric acid as the product; ketoglutarate is a component of the Krebs cycle. In effect, the formation of glycine helps to eliminate an excitotoxin while replenishing the pathway of oxidative metabolism. When collagen is dissolved, a large amount of the antitoxic glycine is released, but not a bit of the excitotoxic antithyroid amino acids cysteine and tryptophan.

The increased energy deficiency produced by accumulated toxins and fibrosis can stimulate the production of porphyrins for the heme enzymes that control respiration and detoxification, and this can lead to the production of carbon monoxide and other anti-respiratory factors. Increasing amounts of ammonia and lactic acid circulate through the tissues. As excitatory states replace the capacity for resting inhibition, increased amounts of many hormones and other signal substances circulate, and many of them are produced in unusual sites, often in the same tissues that respond to them, as when a breast cancer produces estrogen. In the absence of communication between the tissue and its environment, these locally produced factors probably serve to maintain local homeostasis, but at the expense of the functions of the whole organism.

In every different part of the body, the extracellular matrix reflects the individuality of its cell types and their particular function. But as the body's exposure to toxic imbalances progresses, the general properties of deterioration start to become more important than the specialized functions.

To reverse this process, it's necessary to avoid doing the things that caused the problem to develop. The accumulation of heavy metals and of the unstable unsaturated fats (linoleic, linolenic, and arachidonic acids) can be slowed or reversed by careful dietary choices. The calorie-restricted diets that slow the aging process reduce the accumulation of the unstable fats and the heavy metals. Vitamin E reduces the vascular leakiness and the free radical peroxidation that are so closely involved in fibrosis. Since serotonin and nitric oxide are involved in these processes, they should be minimized by keeping carbon dioxide production high (by optimizing thyroid function), and by eating proteins that have a safe balance of the amino acids. Too much arginine increases nitric oxide formation, and too much tryptophan increases serotonin production. Too much glutamic acid aspartic acid, and cysteine can be directly excitotoxic, and the metabolites of cysteine include proinflammatory homocysteine, which can disrupt collagen structure.

Since estrogen is often a promoter of fibrosis, acting in a variety of ways, it should be kept under control by eating enough protein, keeping thyroid function relatively high, and if necessary by using progesterone and other antiestrogenic hormones. A protein deficiency is thrombogenic (clot forming), and probably excitotoxic.

Magnesium, taurine, and niacinamide have many protective functions, and can help to reduce or reverse inflammatory and fibrogenic processes.

Solid tumors must induce new blood vessels if they are to grow beyond minimal size. As an initial step in this process, tumors secrete a vascular permeability factor that renders the local microvasculature hyperpermeable to fibrinogen and to other plasma proteins. Extravasated fibrinogen is rapidly clotted to crosslinked fibrin gel. Over time, this gel is invaded by macrophages, fibroblasts, and endothelial cells and undergoes "organization," such that it is replaced by vascularized granulation tissue and finally by mature connective tissue. This sequence of events is not unique to tumors but occurs in wound-healing and in a wide variety of other disease processes, including some that prominently affect the lung.

March 2001

Mary Shomon interview

Mary Shomon: Why do women with treated hypothyroidism frequently still have inappropriately high levels of cholesterol and high triglycerides, and what can they do to help lower these levels?

RP: Often it's because they were given thyroxine, instead of the active thyroid hormone, but hypertriglyceridemia can be caused by a variety of things that interact with hypothyroidism. Estrogen treatment is a common cause of high triglycerides, and deficiencies of magnesium, copper, and protein can contribute to that abnormality. Toxins, including some drugs and herbs, can irritate or stimulate the liver to produce too much triglyceride. T3, triiodothyronine, is the active thyroid hormone, and it is produced (mainly in the liver) from thyroxine, and the female liver is less efficient than the male liver in producing it, as is the female thyroid gland. The thyroid gland, which normally produces some T3, will decrease its production in the presence of increased thyroxine. Therefore, thyroxine often acts as a "thyroid anti-hormone," especially in women. When thyroxine was tested in healthy young male medical students, it seemed to function "just like the thyroid hormone," but in people who are seriously hypothyroid, it can suppress their oxidative metabolism even more. It's a very common, but very serious, mistake to call thyroxine "the thyroid hormone."

Nov. 6, 2000, email interview with Mary Shomon for her website:
www.thyroid.about.com/library/weekly/aa110800c.htm
References weren't included in the interview.

High cholesterol is more closely connected to hypothyroidism than hypertriglyceridemia is. Increased T3 will immediately increase the conversion of cholesterol to progesterone and bile acids. When people have abnormally low cholesterol, I think it's important to increase their cholesterol before taking thyroid, since their steroid-forming tissues won't be able to respond properly to thyroid without adequate cholesterol.

MS: You feel that progesterone can have anti-stress effects, without harming the adrenal glands. Is progesterone therapy something you feel is useful to many or most hypothyroid patients? How can a patient know if she needs progesterone? Do you recommend blood tests? And if so, at what point in a woman's cycle?

RP: Estrogen blocks the release of hormone from the thyroid gland, and progesterone facilitates the release. Estrogen excess or progesterone deficiency tends to cause enlargement of the thyroid gland, in association with a hypothyroid state. Estrogen can activate the adrenals to produce cortisol, leading to various harmful effects, including brain aging and bone loss. Progesterone stimulates the adrenals and the ovaries to produce more progesterone, but since progesterone protects against the catabolic effects of cortisol, its effects are the opposite of estrogen's. Progesterone has antiinflammatory and protective effects, similar to cortisol, but it doesn't have the harmful effects. In hypothyroidism, there is a tendency to have too much estrogen and cortisol, and too little progesterone.

The blood tests can be useful to demonstrate to physicians what the problem is, but I don't think they are necessary. There is evidence that having 50 or 100 times as much progesterone as estrogen is desirable, but I don't advocate

"progesterone replacement therapy" in the way it's often understood. Progesterone can instantly activate the thyroid and the ovaries, so it shouldn't be necessary to keep using it month after month. If progesterone is used consistently, it can postpone menopause for many years.

Cholesterol is converted to pregnenolone and progesterone by the ovaries, the adrenals, and the brain, if there is enough thyroid hormone and vitamin A, and if there are no interfering factors, such as too much carotene or unsaturated fatty acids.

Progesterone deficiency is an indicator that something is wrong, and using a supplement of progesterone without investigating the nature of the problem isn't a good approach. The normal time to use a progesterone supplement is during the "latter half" of the cycle, the two weeks from ovulation until menstruation. If it is being used to treat epilepsy, cancer, emphysema, multiple sclerosis, migraine or arthritis, or something else so serious that menstrual regularity isn't a concern, then it can be used at any time.

MS:: What supplements do you feel are essential for most people with hypothyroidism?

RP: Because the quality of commercial nutritional supplements is dangerously low, the only supplement I generally advocate is vitamin E, and that should be used sparingly. Occasionally, I will suggest limited use of other supplements, but it is far safer in general to use real foods, and to exclude foods which are poor in nutrients. Magnesium is typically deficient in hypothyroidism, and the safest way to get it is by using orange juice and meats, and by using epsom salts baths; magnesium carbonate can be helpful, if the person doesn't experience side effects such as headaches or hemorrhoids.

MS: Do you feel that there are any special considerations, issues, or treatments for men with hypothyroidism?

RP: Thyroid supplements can be useful for prostate hypertrophy and some cases of impotence and infertility. Occasionally, a man who can't put on a normal amount of weight finds that a thyroid supplement allows normal weight gain. Leg cramps, insomnia and depression are often the result of hypothyroidism. Heart failure, gynecomastia, liver disease, baldness and dozens of other problems can result from hypothyroidism.

MS: Many people describe how they are clinically hypothyroid, with elevated TSH levels, but have extremely high pulse rates. Do you have any thoughts as to what might be going on in that situation?

RP: In hypothyroidism, thyrotropin-release hormone (TRH) is usually increased, increasing release of TSH. TRH itself can cause tachycardia, "palpitations," high blood pressure, stasis of the intestine, increase of pressure in the eye, and hyperventilation with alkalosis. It can increase the release of norepinephrine, but in itself it acts very much like adrenalin. TRH stimulates prolactin release, and this can interfere with progesterone synthesis, which in itself affects heart function.

I consider even the lowest TSH within the "normal range" to be consistent with hypothyroidism; in good health, very little TSH is needed. When the thyroid function is low, the body often compensates by over-producing adrenalin. The daily production of adrenalin is sometimes 30 or 40 times higher than normal in hypothyroidism. The adrenalin tends to sustain blood sugar in spite of the metabolic inefficiency of hypothyroidism, and it can help to maintain core body temperature by causing vasoconstriction in the skin, but it also disturbs the sleep and accelerates the heart. During the night, cycles of rising adrenalin can cause nightmares, wakefulness, worry, and a pounding heart. Occasionally, a person who has chronically had a heart rate of 150 beats per minute or higher, will have a much lower heart rate after using a thyroid supplement for a few days. If your temperature or heart rate is lower after breakfast than before, it's likely that they were raised as a result of the nocturnal increase of adrenalin and cortisol caused by hypothyroidism.

M.S.: You have written that for some people, there is a problem converting T4 to T3, but that

diet can help. You recommend a piece of fruit or juice or milk between meals, plus adequate protein, can help the liver produce the hormone. Can you explain a bit more about this idea and how it works?

R.P.: The amount of glucose in liver cells regulates the enzyme that converts T4 to T3. This means that hypoglycemia or diabetes (in which glucose doesn't enter cells efficiently) will cause hypothyroidism, when T4 can't be converted into T3. When a person is fasting, at first the liver's glycogen stores will provide glucose to maintain T3 production. When the glycogen is depleted, the body resorts to the dissolution of tissue to provide energy. The mobilized fatty acids interfere with the use of glucose, and certain amino acids suppress the thyroid gland. Eating carbohydrate (especially fruits) can allow the liver to resume its production of T3.

M.S.: You have recommended if supplemental T3 is used, a thyroid patients "nibble on a 10-15 mg Cytomel tablet throughout the day." Can you explain why? Would compounded time-released T3 as available in some compounding pharmacies do the same?

R.P.: Most hypothyroid people can successfully use a supplement that contains four parts of thyroxine for each part of T3, but some people need a larger proportion of T3 for best functioning. The body normally produces several micrograms of T3 every hour, but if a large amount of supplementary thyroid is taken in a short time, the liver quickly inactivates some of the excess T3. Taking a few micrograms per hour provides what the body can use, and doesn't suppress either the liver's or the thyroid's production of the hormone. I have only rarely talked to anyone who had good results with the so-called time-release T3, and I have seen analyses of some samples in which there was little or no T3 present. It is hard to compound T3 properly, and the conditions of each person's digestive system can determine whether the T3 is released all at once, or not at all. I don't think there is a valid scientific basis for calling anything "time-release T3."

I have been told that the company which now owns the Armour name and manufactures "Armour thyroid USP" has added a polymer to the formula, and I think this would account for the stories I have heard about its apparent inactivity. Some people have found that the tablets passed through their intestine undigested, so I think it's advisable to crush or powder the tablets.

M.S.: You feel that excessive aerobic exercise can be a cause of hypothyroidism. Can you explain this further? How much is too much?

R.P.: I'm not sure who introduced the term "aerobic" to describe the state of anaerobic metabolism that develops during stressful exercise, but it has had many harmful repercussions. In experiments, T3 production is stopped very quickly by even "sub-aerobic" exercise, probably because of the combination of a decrease of blood glucose and an increase in free fatty acids. In a healthy person, rest will tend to restore the normal level of T3, but there is evidence that even very good athletes remain in a hypothyroid state even at rest. A chronic increase of lactic acid and cortisol indicates that something is wrong. The "slender muscles" of endurance runners are signs of a catabolic state, that has been demonstrated even in the heart muscle. A slow heart beat very strongly suggests hypothyroidism. Hypothyroid people, who are likely to produce lactic acid even at rest, are especially susceptible to the harmful effects of "aerobic" exercise. The good effect some people feel from exercise is probably the result of raising the body temperature; a warm bath will do the same for people with low body temperature.

M.S.: You feel that chronic protein deficiency is a common cause of hypothyroidism. How much protein should people get (as much as 70-100 grams a day?) and what types of protein, in order to prevent hypothyroidism?

R.P.: The World Health Organization standard was revised upward by researchers at MIT, and recently the MIT standard has been revised upward again by military researchers; this

is described in a publication of the National Academy of Sciences (National Academy Press, *The Role of Protein and Amino Acids in Sustaining and Enhancing Performance,* 1999). When too little protein, or the wrong kind of protein, is eaten, there is a stress reaction, with thyroid suppression. Many of the people who don't respond to a thyroid supplement are simply not eating enough good protein. I have talked to many supposedly well educated people who are getting only 15 or 20 grams of protein per day. To survive on that amount, their metabolic rate becomes extremely low. The quality of most vegetable protein (especially beans and nuts) is so low that it hardly functions as protein.

Muscle meats (including the muscles of poultry and fish) contain large amounts of the amino acids that suppress the thyroid, and shouldn't be the only source of protein.

M.S.: You talk about darkness and shorter days of winter as a stress. It's known that more thyroid hormone is needed by some patients during colder weather. Are there other things you recommend patients do to "winterproof" their metabolism?

R.P.: Very bright incandescent lights are helpful, because light acts on, and restores, the same mitochondrial enzymes that are governed by the thyroid hormone. In squirrels, hibernation is brought on by the accumulation of unsaturated fats in the tissues, suppressing respiration and stimulating increased serotonin production. In humans, winter sickness is intensified by those same antithyroid substances, so it's important to limit consumption of unsaturated fats and tryptophan (which is the source of serotonin). When a person is using a thyroid supplement, it's common to need four times as much in December as in July.

M.S.: You have reported that pregnenolone can be helpful for Graves' patients with exophthalmus. Can you explain further?

R.P.: Graves' disease and exophthalmos can occur with hypothyroidism or euthyroidism, as well as with hyperthyroidism. Pregnenolone regulates brain chemistry in a way that prevents excessive production of ACTH and cortisol, and it helps to stabilize mitochondrial metabolism. It apparently acts directly on a variety of tissues to reduce their retention of water. In the last several years, all of the people I have seen who had been diagnosed as "hyperthyroid" have actually been hypothyroid, and benefitted from increasing their thyroid function; some of these people had also been told that they had Graves' disease.

M.S.: You are a proponent of coconut oil for thyroid patients. Can you explain why?

R.P.: An important function of coconut oil is that it supports mitochondrial respiration, increasing energy production that has been blocked by the unsaturated fatty acids. Since the polyunsaturated fatty acids inhibit thyroid function at many levels, coconut oil can promote thyroid function simply by reducing those toxic effects. It allows normal mitochondrial oxidative metabolism, without producing the toxic lipid peroxidation that is promoted by unsaturated fats.

M.S.: Do you have any thoughts for thyroid patients who are trying to do everything right, and yet still can't lose any weight?

R.P.: Coconut oil added to the diet can increase the metabolic rate. Small frequent feedings, each combining some carbohydrate and some protein, such as fruit and cheese, often help to keep the metabolic rate higher. Eating raw carrots can prevent the absorption of estrogen from the intestine, allowing the liver to more effectively regulate metabolism. If a person doesn't lose excess weight on a moderately low calorie diet with adequate protein, it's clear that the metabolic rate is low. The number of calories burned is a good indicator of the metabolic rate. The amount of water lost by evaporation is another rough indicator: For each liter of water evaporated, about 1000 calories are burned.

M.S.: You have talked about internal malnutrition as a problem for many thyroid patients, due to insufficient digestive juices and poor intestinal

movements. Are there ways patients who are treated for hypothyroidism can help alleviate this problem.

R.P.: The absorption and retention of magnesium, sodium, and copper, and the synthesis of proteins, are usually poor in hypothyroidism.

Salt craving is common in hypothyroidism, and eating additional sodium tends to raise the body temperature, and by decreasing the production of aldosterone, it helps to minimize the loss of magnesium, which in turn allows cells to respond better to the thyroid hormone. This is probably why a low sodium diet increases adrenalin production, and why eating enough sodium lowers adrenalin and improves sleep. The lowered adrenalin is also likely to improve intestinal motility.

M.S.: You've mentioned eggs, milk and gelatin as good for the thyroid. Can you explain a bit more about this?

R.P.: Milk contains a small amount of thyroid and progesterone, but it also contains a good balance of amino acids. For adults, the amino acid balance of cheese might be even better, since the whey portion of milk contains more tryptophan than the curd, and tryptophan excess is significantly antagonistic to thyroid function. The muscle meats contain so much tryptophan and cysteine (which is both antithyroid and potentially excitotoxic) that a pure meat diet can cause hypothyroidism. In poor countries, people have generally eaten all parts of the animal, rather than just the muscles--feet, heads, skin, etc. About half of the protein in an animal is collagen (gelatin), and collagen is deficient in tryptophan and cysteine. This means that, in the whole animal, the amino acid balance is similar to the adult's requirements. Research in the amino acid requirements of adults has been very inadequate, since it has been largely directed toward finding methods to produce farm animals with a minimum of expense for feed. The meat industry isn't interested in finding a diet for keeping chickens, pigs, and cattle healthy into old age. As a result, adult rats have provided most of our direct information about the protein requirements of adults, and since rats keep growing for most of their life, their amino acid requirements are unlikely to be the same as ours.

M.S.: Do you think the majority of people with hypothyroidism get too much or too little iodine? Should people with hypothyroidism add more iodine, like kelp, seaweeds, etc.?

R.P.: 30 years ago, it was found that people in the US were getting about ten times more iodine than they needed. In the mountains of Mexico and in the Andes, and in a few other remote places, iodine deficiency still exists. Kelp and other sources of excess iodine can suppress the thyroid, so they definitely shouldn't be used to treat hypothyroidism.

M.S.: What are your thoughts for Graves' disease/hyperthyroidism patients? Should they move ahead quickly to get radioactive iodine treatment, or are there natural things they might be able to try to temporarily – or even permanently – get a remission?

RP: Occasionally, a person with a goiter will temporarily become hyperthyroid as the gland releases its colloid stores in a corrective process. Some people enjoy the period of moderate hyperthyroidism, but if they find it uncomfortable or inconvenient, they can usually control it just by eating plenty of liver, and maybe some cole slaw or raw cabbage juice. Propranolol will slow a rapid heart. The effects of a thyroid inhibitor, PTU, propylthiouracil, have been compared to those of thyroidectomy and radioactive iodine. The results of the chemical treatment are better for the patient, but not nearly so profitable for the physician.

Besides a few people who were experiencing the unloading of a goiter, and one man from the mountains of Mexico who became hypermetabolic when he moved to Japan (probably from the sudden increase of iodine in his diet, and maybe from a smaller amount of meat in his diet), all of the people I have seen in recent decades who were called "hyperthyroid" were not. None of the

people I have talked to after they had radioiodine treatment were properly studied to determine the nature of their condition. Radioiodine is a foolish medical toy, as far as I can see, and is never a proper treatment.

Endocrinol Jpn 1977 Jun;24(3):271-6 **Effect of thyrotropin releasing hormone on heart rate and visual evoked potentials in rats.** Tonoue. The effect of injection of 0.3 microgram of thyrotropin releasing hormone (TRH) into the third ventricle on heart rate and photically evoked potentials in the midbrain reticular formation in urethane-anesthetized rats was studied. TRH increased the heart rate and amplitude of the visual evoked potentials within a few minutes following injection. The intraventricular injections of LHRH, consituent amino acids of TRH and intraperitoneal TSH did not exert any effect. This indicates that TRH is effective in the central nerveous system in inducing tachycardia in the rat.

Eur Heart J 1987 May;8 Suppl B:147-51 **Injection of thyrotropin releasing hormone into the locus coeruleus increases blood pressure.** Paakkari I, Siren AL, Nurminen ML, Svartstrom-Fraser M. Thyrotropin releasing hormone (TRH), 10 pmol kg-1 injected in the region of locus coeruleus, caused a rapid (within 1 min) rise of mean arterial pressure in **the urethane-anaesthetized rat. No clear-cut effects in heart rate or ventilation were observed. When TRH was injected into the lateral ventricle, a dose more than 10-fold higher was required to achieve a comparable rise in arterial pressure. It is concluded that TRH may have a physiological role in central cardiovascular regulation.**

Horm Metab Res 1987 Apr;19(4):164-7. **Cardiovascular, catecholamine and psychological responses to TRH in four types of affective disorder patients.** Kennedy B, Strassman RJ, Ziegler MG, Janowsky DS, Risch SC, Huey LY, Gillin JC When 500 micrograms of TRH is given intravenously, an increase in TSH, blood pressure, plasma catecholamines and positive emotions follows. Four groups of patients with major, minor or bipolar depression or schizoaffective disorder increased their TSH levels by similar amounts after TRH. The neurohormone also significantly increased diastolic blood pressure by 5.5 +/- 1.6 mm Hg, and decreased heart rate by 7.6 +/- 1.3 beats/min. There was a weak trend for bipolar depressives to have less cardiovascular response to TRH than the other **groups. Plasma norepinephrine (NE) was higher after TRH than after placebo. The NE response differed between patient groups (P = .0023) because of a smaller** response by major depressives. TRH decreased anger, tension and depression, and increased friendliness. Positive emotional responses were significantly greater in the bipolar depressives than in other groups. Forty-one other studies have found a subnormal TSH response does not distinguish between subtypes of the affective disorders, but cardiovascular, catecholamine and mood responses may do so.

Acta Physiol Scand 1983 Mar;117(3):427-37. **Effects of TRH and TRH analogues on the central regulation of breathing in the rat.** Hedner J, Hedner T, Wessberg P, Lundberg D, Jonason J Respiratory activity was studied in rats during light halothane anesthesia. Thyrotropin releasing hormone (TRH) and two TRH analogues: the desamidated form (TRH-OH) and gamma- butyrolactone- gamma-carbonyl-L-histidyl-L-prolinamide citrate (DN 1417) were administered intracerebroventricularly. TRH 0.5-5 micrograms induced a marked tachypnoea with a rapid onset and a duration of at least 20 min. DN 1417, a potent analogue of TRH with a very low TSH (thyroid stimulating hormone) releasing activity was more effective in stimulating respiratory frequency, while TRH-OH, regarded to have neither TSH releasing nor extra hypothalamic effects, at equimolar doses was unable to induce any changes in the respiratory pattern. When TRH was given into the fourth ventricle the dose response curve was slightly shifted to the left. In experiments employing the occluded breath technique, P0.1 was increased in the same magnitude as the mean inspiratory flow (VT/T1). The results also indicated an increase in the gain of the inflation reflex loop whereas the central bulbopontine setting for T1 and TTOT were not significantly changed. Local injection of TRH into the nucleus tractus solitarii induced a stimulation of respiratory frequency which was slower in onset compared to the response seen after injection into the lateral or fourth ventricles. Concomitantly to the respiratory changes, i.c.v. TRH **injection induced a hypocarbia and an alkalosis. No changes in blood pressure** or heart rate were seen. The respiratory stimulant effect of TRH could be potentiated by pretreatment with naloxone, methylatropine or a low dose of GABA. Haloperidol or propranolol did not significantly change the respiratory effects of TRH, while reserpine pretreatment seemed to blunt some of the ventilatory effects of TRH. It seems likely that TRH has few direct effects on brain stem neurones involved in the central regulation of respiration, but the main effects seem to be elicited in areas rostral to the brain stem. The respiratory stimulating effect of TRH is unrelated to TSH. Furthermore, other neurotransmitter systems might also be involved in modulation of the respiratory stimulation evoked by TRH.

Invest Ophthalmol Vis Sci 1989 Oct; 30(10): 2200-8. **Thyrotropin releasing hormone increases intraocular pressure. Mechanism of action.** Liu JH, Dacus AC, Bartels SP. Eye Research Institute of REtina Foundation, Harvard Medical School, Boston, Massachusetts. Intravenous injections of 1-100 micrograms thyrotropin releasing hormone (TRH) in rabbits elevated intraocular pressure (IOP). The 2-5 mm Hg increase of IOP lasted for less than 2 hr. No change of pupil size was observed. This IOP elevation was not due to a direct effect of TRH on ocular tissues since intravitreal injections of 0.1 and 1 micrograms TRH did not change IOP. Concentrations of thyroid stimulating hormone (TSH), triiodothyronine (T-3), epinephrine (Epi) and norepinephrine (NE) in the plasma were elevated at 30 min after an i.v. injection of 10 micrograms TRH. Plasma levels of prolactin and thyroxine were not changed. Bolus i.v.

injections of 0.1-1 micrograms TSH and 0.1-1 micrograms T-3, which would produce an equivalent increase of relevant hormones in the circulation, did not increase IOP. However, similar i.v. injections of 10-100 ng Epi and 100 ng NE caused a 1.5-3 mm Hg IOP elevation for 15-30 min. Thus, the IOP elevation following TRH administration probably is caused by the increase of circulating endogenous catecholamines and not by the stimulation of the TSH-thyroid hormone axis. Heart rate, but not blood pressure, was increased with 10 micrograms TRH. After unilateral transection of the cervical sympathetic trunk, the IOP elevation in the decentralized eye was larger than that in the intact eye. Topical treatment of 0.1% or 1% timolol in the decentralized eye inhibited the IOP elevations in both eyes, but 0.1% prazosin was not effective. **Topical 1% atropine and atropine given subcutaneously at 0.6 mg/kg decreased the bilateral IOP elevations. These observations indicate that beta-adrenergic and muscarinic mechanisms,** not an alpha-1-adrenergic mechanism, are involved.

Peptides 1990 Sep-Oct;11(5):939-44. **Selective cardiorespiratory activity of an iodinated analog of thyrotropin-releasing hormone (TRH).** Paakkari I, Jarvinen A, Vonhof S, Mannisto PT, Cohen LA, Labroo VM, Feuerstein G. The biological activity of thyrotropin-releasing hormone (TRH) and its analogs 4(5)-I-Im-TRH and 2,4(5)-I2-Im-TRH was assessed by means of their effects on: 1) the mean arterial pressure (MAP), 2) heart rate (HR), 3) ventilation minute volume (MV), 4) contractility of the rat duodenum, and 5) concentrations of thyrotropin (TSH) or prolactin (PRL) in serum. Also their binding to TRH-receptors in brain homogenates was studied. In urethane-anesthetized rats TRH ICV increased MAP, HR and MV. 4(5)-I-Im-TRH was equally as active as TRH on HR and MV but a significant elevation in MAP was observed only at a dose 100-fold to that of TRH. However, the maximal responses of 4(5)-I-Im-TRH and TRH did not differ. **In conscious rats, TRH 1A elevated MAP and HR** but 4(5)-I-Im-TRH was active on MAP only. 2,4(5)-I2-Im-TRH was devoid of cardiorespiratory activity. **TRH dose-dependently inhibited the contractions of the rat duodenum** while the iodinated analogs lacked such an activity. To induce a significant release of TSH several hundred times more of 4(5)-I-Im-TRH and over 1000 times more of 2,4(5)-I2-Im-TRH were needed as compared to TRH. The iodoanalogs elevated PRL levels only at doses 2000-fold higher than those of TRH. The iodoanalogs displaced [3H][3-Me-His2]TRH [(3H]MeTRH) from its binding sites at concentrations about 1000 times higher than those of TRH. Substitutions of the histidyl moiety of TRH in 4(5)-I-Im-TRH and 2,4(5)-I2-Im-TRH resulted in substantial loss of the endocrine activity. While the di-iodinated analog was **practically devoid of any biological activity the monoiodinated analog exerted similar cardiorespiratory activity to that of TRH.**

Arch Gen Psychiatry 1991 Feb;48(2):148-56. **Endocrine, cardiovascular, and behavioral effects of intravenous protirelin in patients with panic disorder.** Stein MB, Uhde TW Section on Anxiety and Affective Disorders, National Institute of Mental Health, Bethesda, Md 20892. The effects of protirelin administration on the anterior pituitary release of thyrotropin and prolactin were examined in 26 patients with panic disorder and 22 healthy volunteers. There were no differences observed in hormonal responses to protirelin between patients and controls. However, higher Beck Depression Inventory scores were associated with smaller baseline-corrected maximal changes in thyrotropin responses. Cardiovascular responses to protirelin did not differ between a subgroup of 15 patients with panic disorder and 15 age- and **sex-matched healthy controls. Although protirelin produced robust increases in heart rate and blood pressure, only one patient with panic disorder experienced** a panic attack during the infusion. The hormonal findings suggest that the presence of depressive symptoms may have a significant impact on various indexes of neuroendocrine responsivity and should be taken into consideration when looking at biologic measures in patients with panic disorder. The cardiovascular and behavioral findings do not support the hypothesis that all panic-producing stimuli are nonspecific and suggest that the induction of physical stimuli may be insufficient to produce panic attacks even in susceptible individuals.

Exp Clin Endocrinol 1992;99(3):143-6. **Time-related effects of thyrotropin-releasing hormone (TRH) on the pituitary-thyroid axis and extrathyroidal targets.** Nink M, Weber P, Krause U, Beyer J IIIrd. Thyrotropin-releasing hormone (TRH) is a tripeptide and acts as a stimulator of the pituitary-thyroid axis as well as having a great number of well defined extrathyroidal functions. Studies in experimental animals have shown, that TRH also has a role as a neuromodulator within the autonomous nervous system. In this study we analyzed the effects following peripheral administration of TRH (200 micrograms, 400 micrograms) in patients with endocrinological disorders and in healthy females and males. By means of a questionnaire, patients were asked about possible (side-) effects; ventilatory and cardiovascular monitoring was performed during steady state. The pulsatile TSH-secretion pattern was analyzed and thyroid and stress hormones were measured in the blood prior to and following TRH i.v. Frequent symptoms afer TRH were feeling of heat (58%), **stimulation of respiration (61%), palpitations (39%), micturition urge (52%) and restlessness (32%). Apparative monitoring demonstrated a short stimulation of respiration and an increase of heart rate. After 400 micrograms TRH i.v., blood levels of ACTH decreased slightly (p less than 0.01) but levels of T3, T4,** epinephrine, norepinephrine and cortisol remained unchanged (p greater than 0.05). TSH-levels were low during daytime and showed a surge at night.

Am J Cardiol 1994 Feb 15;73(5):374-8. **Usefulness of L-thyroxine to improve cardiac and exercise performance in idiopathic dilated cardiomyopathy.** Moruzzi P, Doria E, Agostoni PG, Capacchione V, Sganzerla P. "The short-term effects of L-thyroxine (100 micrograms/day, 10 patients) and placebo (10 patients) on idiopathic dilated cardiomyopathy were compared." **"A decrease in resting**

systemic vascular resistances and an increase in cardiac output ($p < 0.05$) were also observed. Cardiopulmonary effort parameters improved ($p < 0.05$) without hemodynamic changes at peak exercise. It is concluded that L-thyroxine short-term administration improves cardiac and exercise performance in patients with chronic heart failure, without modifying the adrenergic support to the heart and the circulatory parameters at peak exercise."

J Steroid Biochem 1983 Jul;19(1B):433-8. **Effects of anterior pituitary hormones and their releasing hormones on physiological and behavioral functions in rats.** Lin MT, Ho LT, Uang WN "The effects of direct administration of TRH, TSH, LHRH, LH, ACTH, GH, FSH and prolactin into cerebral ventricle system on metabolic, respiratory, cardiovascular and behavioral responses were assessed in unanesthetized rats, **Intraventricular administration of TRH, TSH, LHRH or LH caused hypothermia, decreased metabolism and/or cutaneous vasodilation at room temperature (22 degrees C)."** "In addition, intraventricular administration of TRH, LHRH or LH caused tachycardia, hypertension and a reduction in the epinephrine-induced reflex bradycardia." "Furthermore, following intraventricular administration of **TRH, but not TSH, LHRH, LH, FSH, GH, ACTH or prolactin three main categories of behavior were provoked: activity of normal type--forward locomotion stimulation, head and body rearing; stereotype activity--increased grooming and head swaying; and abnormal type behavior--tail elevation and piloerection in rats."**

Indian J Physiol Pharmacol 1984 Apr-Jun;28(2):153-8 **A study of pituitary-thyroid function during exercise in man.** Sawhney RC, Malhotra AS, Gupta RB, Rai RM "Exercise induced modulations in circulatory T4, T3 and TSH were monitored in 14 healthy euthyroid male volunteers undergoing exercise on a bicycle ergometer at 750 KPM for 20 minutes." "Serum T4 exhibited a significant decrease (P less than 0.05) from 9.6 +/- 0.49 microgram/dl (mean +/- SE) to 8.3 +/- 0.47 microgram/dl at 20 min after the termination of the exercise, whereas a significant decrease (P less than 0.01) in T3 levels from 158 +/- 9 ng/dl to 144 +/- 8.2 ng/dl was recorded at 40 min after the termination of the exercise." "These observations suggest that hormone **secretion by the thyroid and its responsiveness to endogenous TSH are maintained after exercise. The decrease in circulatory T4 and T3 could be due to an increase in degradation of the hormones or may reflect a generalized adaptation phenomenon. The exact mechanism and significance of these alterations remains to be elucidated."**

Arch Intern Med 1984 Jun;144(6):1149-52 **Diagnostic dosages of protirelin (TRH) elevate BP by noncatecholamine mechanisms.** Zaloga GP, Chernow B, Zajtchuk R, Chin R, Rainey TG, Lake CR "While performing thyroid function tests, we noticed that protirelin (TRH) raised BP, and, therefore, we investigated the effect of diagnostic dosages of protirelin (500 micrograms) on plasma catecholamine levels and cardiovascular function in eight patients one day before, one day after, and four weeks following heart surgery. **Mean arterial pressure (MAP), heart rate (HR), plasma norepinephrine (NE), epinephrine (EPI), dopamine (DA), thyroid hormone (triiodothyronine [T3], thyroxine), and thyrotropin (TSH) levels were measured before and after the intravenous injection of protirelin. Protirelin increased MAP transiently from 88 +/- 2 to 103 +/- 3 mm Hg (before surgery), 86 +/- 4 to 102 +/- 4 mm Hg (one day after surgery), and 86 +/- 4 to 104 +/- 5 mm Hg (four weeks after surgery)."** "We conclude the following: (1) **diagnostic dosages of protirelin transiently elevate MAP and SVR by a noncatecholamine mechanism, (2) clinicians who perform protirelin tests should be aware of protirelin's transient pressor effects."**

Endocrinologie 1982 Jul-Sep;20(3):165-76. **Endocrine circadian time structure in the aged.** Nicolau GY, Haus E, Lakatua DJ, Bogdan C, Petrescu E, Sackett-Lundeen L, Berg HG, Ioanitiu D, Popescu M, Chioran C "Thirteen circadian rhythms in plasma hormone levels (ACTH, aldosterone, cortisol, C-peptide, insulin, DHEA-S, estradiol, LH, prolactin, 17-OH progesterone, testosterone, T4 and TSH) were studied in April 1981 in 25 males and 25 females 57 to 91 years of age, institutionalized at the Berceni Hospital for the aged." "In comparison with previous data from the Endocrine Rhythms Laboratory ("C. I. Parhon" Institute) and series of younger subjects studied in Minnesota (St. Paul-Ramsey Medical Center) as well as in comparison with data published from other centers, the aged **seem to experience an earlier arousal of their endocrine system which may be related to certain disturbances of old age e.g. of sleep."**

Clin Endocrinol (Oxf) 1988 Jul;29(1):63-75. **A double-blind cross-over 12-month study of L-thyroxine treatment of women with 'subclinical' hypothyroidism.** Nystrom E, Caidahl K, Fager G, Wikkelso C, Lundberg PA, Lindstedt G. "Twenty women, who had been randomly selected from women with subclinical hypothyroidism identified in a population study were treated with L-thyroxine and placebo in a double-blind cross-over design during 2 x 6 months." "Heart rate-corrected preejection period and symptom score **decreased (P less than 0.05). Four women starting with L-thyroxine showed a marked and prolonged (4-6 months) rise in thyrotrophin concentration during the subsequent placebo period, but remained clinically euthyroid." "Subclinical hypothyroidism is common among middle-aged and old women, and our findings indicate that approximately one woman in four with this 'subclinical' condition will benefit from L-thyroxine treatment."**

Sketch of some of the broader concepts needed in aging theory:

Estrogen increases with aging, and the characteristic changes of aging---including menopause, glucose intolerance/insulin resistance, autoimmunity and inflammatory dysregulation, respiratory decline, susceptibility to cancer, connective tissue hardening and slowed cellular responses---are produced by prolonged exposure to estrogen.

Radiation, cholera toxin, and a variety of stressors synergize with or imitate estrogen.

Estrogen is just one of the intrinsic excitatory substances, which are produced by stress, and which participate in self-stimulating loops.

Energy depletion, free-radical generation, and gene mutations are produced by estrogen and by the nitric oxide (NO) promoted by estrogen.

Estrogen and nitric oxide activate the pituitary, in just one of many vicious circles of self-stimulation.

Carbon dioxide produced in the high energy state provides direct protection of protein structure against random chemical changes. These protective effects occur within cells, between cells, and in the extracellular "ground substance" or matrix, in which cells are embedded. Thyroid and progesterone support CO2's protective effects.

Ammonia is one of the factors promoted by estrogen and other stressors, in competition with carbon dioxide.

Ammonia is pro-inflammatory. With NO (nitric oxide), TNF (tumor necrosis factor), glutamate, and calcium, it activates cells while interfering with their energy. *In vitro*, ammonia and lactate clearly poison cells (contributing to the myth of "programmed aging.")

The "little mouse," and the experiments of Denckla and Everitt, show that a simple growth hormone deficiency or lack of pituitary function can double the life span. Intervention in the many other self-stimulating excitatory pathways can produce additional retardation of the aging process, acting at many levels, from the extracellular matrix to the brain.

Estrogen, Aging, Radiation, Migraine & Energy

The Manhattan Project demonstrated that, by spending a couple of billion dollars, a very impressive explosion could be created by exploiting the unsurprising fact that, in the presence of a sufficient mass of suitable material, spontaneous radioactivity becomes self-stimulating. Part of the taxpayers' money was spent on convincing the public that the bomb was a natural outcome of the fundamentally humanistic scientific enterprise which would give everyone free electricity and a generally glorious life.

Now that we have genetically modified foods, and gamma-irradiated meats and vegetables, maybe it's time to evaluate the process that has led us to these technologies. By seeing how we arrived at our present scientific-technological state, I think many seemingly unrelated scientific and medical issues will take on new meaning, and I think this historical context will justify some reorientations in therapy.

Albert Einstein's name is often associated with the Manhattan Project, but years earlier he departed from the statistical world-view, the assumption of metaphysical randomness, that has characterized "quantum physics," as well as nuclear physics. During the years in which metaphysical randomness took over official physics, that world-view was also being applied to genetics. Eugenics and Racial Hygiene reached their peak almost simultaneously with the realization of the Atomic Bomb (or Tomic Bomb, as F. Soddy more correctly called it). Precisely the same mathematical formulas were used to describe nuclear fission and genetic mutation.

Young physicists from the Manhattan Project, with government financing, smoothly made a transition into genetics, becoming, almost

mysteriously, leaders in the field of "molecular biology." Government subsidies for the nuclear power industry were becoming government subsidies for the industrialization of biology.

The prestige of their background as Manhattan Project physicists made it unnecessary for them to learn anything about biology. As their institutes of molecular biology took over biology departments in the 1960s, they were able to control what was being taught to both undergraduate and graduate biology students.

The physics and physical chemistry that were really relevant to biology, that had been developed before the government/industry consortium took over, were effectively suppressed. If old science journals and monographs didn't just disappear, they were put into "storage," where they couldn't be browsed. At UCLA, for example, you have to place an order for a specific journal, and then wait days for someone to search for the book. Computerized data-bases simply ignored the older work, even though the volume of research published throughout the world in 1930 or 1950 would be similar to the amount currently published in a week or month.

The head of Oregon's Institute of Molecular Biology argued that science develops by its own logic, and can't be blamed for the anti-humanistic ways in which it is used. Since, as a Manhattan Project physicist, he didn't have any knowledge of biology or of other branches of physical science, he couldn't be aware of the powerful ways in which science was distorted by industrial and military intervention. Science, as an ideal, of course can't be blamed for the anti-scientific absurdities that have been sold to the public in the name of science.

First, a philosophy of atomistic reductionism told people that they must give up ideas of teleology, anthropomorphism, purpose, direction, consciousness, and holism, as archaic metaphysical and unscientific concepts. Then, in this cultural vacuum, it was possible to impose the metaphysic of control and of technological improvement, an accountant's metaphysics of the bottom line, which always looks for the quickest return and the most discrete result. The doctrine of genetic determinism was intrinsic to the Eugenics movement: The proper authorities could improve the race by killing the inferior specimens, because it is in the (random) nature of the world that things would degenerate if the fit weren't preserved and the unfit destroyed. The mathematical treatment of random events has no place for the complexities of context, and so is perfect for a system in which the only issue is the power to control for an immediate benefit. Ecology and physiology were marginalized by their very complexity.

These doctrines of random mutation, and of "hygienically" killing the deviant cells, took over cancer biology, with governmental financing.

There was no shortage of evidence that contradicted the idea that cancer arises as a single mutant cell, but few people are now aware of that evidence. Harry Rubin is one of the few people remaining who understand the evidence, and build on it.

The definition of a gene has been revised many times. Originally, a gene was something that produced "a trait," and then it was said to be the "functional unit of heredity." Currently, it is often stated as "the section of DNA that contains the information for making a functonal biological product, which may be a protein or an RNA molecule." But, informally, the traditional view is often passed on, leading many people to think that each protein has "its gene."

The dogmatic view (once taught by molecular geneticists) that "one gene produces one protein" has falsified everything in biology: In reality, the environmentally responsive changes in the composition of proteins means that there are a multitude of different "growth hormones," "prolactins," "interleukins," "hormone receptors," etc. Stress and aging cause cumulative deviations through this process of chemical differentiation.

Rather than seeing cancer (or aging or various degenerative diseases) as a special problem in developmental biology, governed by complex interactions of cells with their environment, **the doctrine of the deviant mutant cell has become an excuse for gross biological ignorance.**

Chronic irritation used to be emphasized as a cause of cancer, but all of the irritating factors were reduced to mutagenic factors, and this made it possible to devalue the tissue changes produced by chronic injury, which preceded and accompanied the development of cancer.

Tissue fibrosis, which was associated with both inflammation and atrophy of injured tissues, became separated from the study of cancer, because it was a complex physiological process, and not a distinct genetic event.

But changes in the connective tissue matrix were always crucially involved in the process of cancerization, and these changes overlapped with the changes that could be seen in many other biological processes.

Ionizing radiation produces inflammation, edema, over-production of collagen, and finally atrophy and fibrosis, with hardening of the collagen and slowing of repair processes. In the atrophic tissue, cancer sometimes develops. Many other harmful agents produce very similar sequences of tissue changes--heat, suffocation, malnutrition, chemical poisoning, and estrogen excess, for example.

The role of the balanced, or imbalanced, tissue environment in carcinogenesis can be seen very clearly in an experiment in which small sheets of plastic were implanted in animals. Near some of the sheets, nests of cancer cells would develop, but they always developed in a concavity that had been formed by the folding of the plastic sheet, almost isolating some cells from their normal environment. This experiment was reminiscent of the experiments of Hans Selye's, in which he found that the tissue which had grown into small subcutaneously implanted glass tubes aged much more rapidly than the rest of the animal's tissues.

The changes of aging are so similar to those of radiation damage that some people have believed that aging was caused by environmental radiation, or at least that radiation accelerates normal aging. The first isn't true, the second is probably approximately true. Anything that produces inflammation, increasing collagen production and collagen hardening, and that slows tissue renewal, is accelerating changes that seem characteristic of aging. But the idea that radiation produces aging by creating mutations has been very clearly refuted. Molecular biologists generally lost interest in the age-accelerating effects of raditation when they saw it wasn't acting through genetic mutations.

Ultraviolet damage to the skin causes changes in the extracellular connective substance that are very similar to aging, but that can be distinguished from the normal age changes by slight differences in the chemistry of the cross-links that make the tissue more rigid. For practical purposes, though, the similarities are more important than the differences.

The "collagen theory of aging" was the idea that the changes which occur in the extracellular matrix (of which collagen is only one component) lead to progressive changes in cellular metabolism, shutting off their access to the blood stream, and that these changes in the matrix are the essential cause of aging. The differences in thickness and flexibility between tanned cowhide and calf-skin, the toughness of meat from old animals, and the rigidity of ligaments in old joints make it obvious that connective tissue changes are characteristic of aging.

Some people who advocate the collagen theory of aging believe that the cross-links that accumulate with age are mainly produced by free radicals (which may be derived from peroxidized lipids, heavy metals, radiation, or ascorbic acid, for example), but others emphasize the role of glucose in forming the links, since diabetes accelerates the hardening of collagen.

In scar tissue, calluses, keloids, and oil granulomas or allergic granulomas, tissue injury or stress has produced structural changes. Tissue stress affects the structure of connective tissues very generally. Tendons and bones are guided and altered in their development by pressure and tension. Histologists have said that they can distinguish structural differences in the bones of wild animals and tame animals of the same species, apparently resulting from the differences in their way of life.

Cellular and extracellular responses are interactive, so that stressed cells produce defective extracellular matrix, which can contribute to the stress of the cells. Changes induced by stress in

some cases interfere with the proper differentiation of cells regulated by their extracellular matrix.

In early studies of estrogen-treated animals, estrogen was found to cause tremendous increases in the deposition of collagen. In the 1960s, detailed studies on the hardening of tendons with aging were done. **It was discovered that estrogen treatment accelerated the stiffening of tendons that normally occurs with aging,** and that progesterone reversed the estrogen effect.

On the level of the whole organism, stress causes overactivity of the pituitary, **and removal of the pituitary extends life, and retards the hardening of the extracellular connective material (Everitt, et al., 1983). The collagen theory of aging necessarily involves the endocrine system.**

When I was measuring the oxygen consumption of uterine tissue from animals of different ages, I found that tissue from some of the oldest animals had what appeared to be "negative oxygen consumption," that is, some gas was being produced at a higher rate than oxygen was being produced, increasing the volume or pressure of the air in the chamber, instead of decreasing it. Since I knew that fatigued nerve and muscle emit some ammonia, I arranged my experiment so that both carbon dioxide and ammonia would be absorbed from the air, and found that these tissues were actually consuming oxygen at a much higher rate than tissues from young animals. While the uterus of a young animal is flexible and bright pink, the uterus from a typical old animal was stiff and purple or blue, indicating an oxygen deficiency. Apparently, their high rate of oxygen consumption was creating a relatively hypoxic condition in the aged uterus. (The rest of my research had to do with identifying the nature of this oxygen consumption; estrogen stimulates the "NADH-oxidase" enzyme function, which---like age-pigment itself---can create a short-circuit between oxygen and the NADH energy source. This serves the purpose of allowing glycolysis to continue in the absence of normal mitochondrial functioning, and probably interferes with normal mitochondrial production of ATP, CO_2, etc., by competing for the oxygen supply.)

Estrogen is known to decrease liver glycogen storage, while progesterone increases it. If a tissue is stimulated to metabolize at a high rate, especially without an adequate supply of glucose, it will consume protein as fuel, with the production of ammonia. Apparently, what I saw in my experiments with the old uteri was a consequence of combining a high level of stimulation with a low level of glucose and oxygen. In nerves, this would be called excitotoxicity.

Although there are several ways in which estrogen can increase the formation of ammonia, just producing hypoxia is sufficient to cause a large increase in ammonia production. **Any exaggerated stimulation, stress, or energy deficit tends to increase the level of ammonia in tissue.** Because of the association of ammonia with energy depletion, many people argue that the ammonia released from nerve and muscle comes primarily from the breakdown of ATP, leading to the deamination of adenosine. But by 1970 there was already clear evidence for other important sources of ammonia. The use of amino acids for fuel, which happens during stress, releases ammonia. **Eating isolated amino acids, exercising intensely, or having an excess of cortisol, causes tissue proteins to be broken down, with the release of ammonia.** Although the free amino acid, glutamate, can be combined with ammonia to remove it safely from cells, ammonia can also be combined with the glutamic acid (or aspartic acid) groups in tissue proteins. **This binding of ammonia to an acid is called amidation.**

When I have written about the importance of carbon dioxide, I mentioned that it binds to amino groups (often lysine) in proteins, protecting those groups from combination with sugars (glycosylation) or the products of lipid peroxidation. Peptide hormones and antibodies function very differently when they have been glycosylated. The lysine groups, that are so important for carbon dioxide's protective effects, are important sites for the cross-linking reactions in collagen, and one form of cross-linking involves the connection of a glutamine group in one protein with the lysine group in another.

Amidation and deamidation occur fairly massively during fatigue and rest in brain proteins, and in many other systems. The activities of proteins are changed as a consequence, but there has been very little research into this important area, because the dogma that "one gene produces one protein" has created the sense that there is something unwholesome about these protein-modifying complexities. Nevertheless, **it is clear that inflammation, connective tissue aging, keratinization, and antigenic changes of tissues and proteins (relevant to autoimmunity and "connective tissue diseases" as well as normal development) are influenced by amidation.**

Estrogen causes epithelial cells to cornify or keratinize (condensing, and being converted mainly into the "horny" material, keratin) earlier than they would otherwise. This process of final differentiation normally occurs as the cells of the skin or mucous membrane grow outward, away from the blood vessels that supply them with nutrients and oxygen. Simply growing away from their supporting blood vessels creates a stress of deprivation. Vitamin A is one of the factors that opposes estrogen and prevents premature keratinization of epithelial cells.

The same enzymes that keratinize cells under the influence of estrogen, and that participate in the solidification of blood clots and the contraction of connetive tissue in healing wounds, can also cross-link collagen molecules.

One of the molecules forming the crosslink bond is glutamine, which exists normally in proteins, but which can also be formed by the addition of ammonia to the acidic side-chain of glutamic acid. The other amino acid that reacts to form the cross-link bond is lysine, which can be protected against chemical reactions by combining with carbon dioxide, This protective effect of carbon dioxide is probably as widely distributed as is lysine in protein, though even when a lysine group isn't exposed, all proteins have an amino group at one end that can interact with carbon dioxide or other substance. **Hormones and their "receptors," enzymes, and structural proteins all exist in multiple forms. The genetic dogma that "one gene corresponds to one protein" has been extremely misleading, and has allowed most researchers to ignore the processes that dominate physiological adaptation.**

Oxygen deprivation is enough to stimulate collagen synthesis (Chvapil; 1968, 1969, 1975), and is probably one of the common factors in tissue degeneration. **Estrogen excess tends to reduce the availability of oxygen in tissues, and oxygen deprivation in many cases imitates estrogenic stimulation.** .The ammonia produced in stressed tissues contributes to changes in collagen and the extracellular matrix, and has both local and systemic effects.

Ammonia, like estrogen, promotes the excitotoxic processes, activating the production of nitric oxide (NO), and stimulating the glutamate receptors, sometimes causing seizures, and if prolonged, causing stupor or coma. But it always activates the pituitary, and in other tissues, the production of free radicals causes molecular tissue damage. The stressors produced by estrogen, for example NO and growth hormone, activate the enzyme aromatase, which synthesizes estrogen, in just one of the many vicious circles. Growth hormone tends to increase ammonia levels.

Estrogen is just one of the intrinsic excitatory substances, which are produced by stress, and which participate in self-stimulating loops. Ammonia and nitric oxide are two of the most pervasive endogenous excitants and toxins. "NO [nitric oxide] is emerging as an important endogenously-derived neurotoxin" (Dawson and Dawson, 1995).

Ammonia, like nitric oxide, inhibits respiration, and can increase the Crabtree effect (with aerobic glycolysis stimulated by increased glucose, inhibiting respiration). This suggests an important role for it in cancer in general, and especially in liver cancer. In the uncontrolled glycolysis of cancer, ammonia can be used to form amino acids from the lactate and pyruvate produced by glycolysis, supporting growth of the tumor at the expense of the normal tissues that are producing ammonia by protein degradation.

Ammonia can produce both convulsive seizures and stupor or coma, and it alters brain

cells, shifting the balance toward that seen in Alzheimer's disease.

Ammonia contributes to the hypertrophy of damaged kidneys, and the same mechanism, decreased protein breakdown in the presence of too much ammonia, probably contributes to the increased volume of extracellular matrix that occurs in so many diseases of stress, aging, and hyperestrogenism.

Ammonia has also been found to be increased during migraine attacks. I suspect that progesterone's sometimes dramatic effect on migraine involves ammonia and energy metabolism. Ammonia disturbs carbon dioxide's regulation of brain circulation, and when ammonia is "detoxified" into glutamine (though glutamine is still toxic in excess) ATP is consumed, leading to dysregulation of vascular smooth muscle. Progesterone's ability to stop the local excitation of nerve cells spares ATP. It seems likely that nitric oxide, the production of which is inhibited by progesterone, is also involved in the vasodilation and energy depletion.

Almost any sort of liver disease increases the systemic ammonia level. Estrogen can cause a large variety of liver diseases, including fatty liver and cholestasis; ammonia, which is toxic in itself, also links into another potentially toxic system, the porphyrin synthetic system.

Porphyria (acute intermittent porphyria, hepatic porphyria) is a disease that can cause nerve damage, hypertension, and connective tissue damage. It typically involves an excess of two precursors of heme, and sometimes a deficiency of heme (needed for respiratory enzymes), and it is often triggered by hypoglycemia, by exercise, and by estrogen or by certain poisons. Although it is usually described as a strictly genetic disease, it is highly susceptible to environmental influences, and a proper reevaluation of the evidence might show that it is more often environmental than genetic. Most of the evidence for a genetic cause consists of measurements that show low activity of certain enzymes. Since the conditions prevailing when a protein is synthesized can affect its structure and functions, the simple measurement of enzyme activity is hardly an appropriate argument.

The two substances that accumulate happen to be in a synthetic sequence, subsequent to a step in which CO2 is removed, and before a step in which NH3, ammonia, is removed. The principle of mass action indicates that a reaction will slow or stop when there is a certain concentration of the product of the reaction. High CO2 and low NH3 will prevent an accumulation of these chemicals, one of which is a potent neurotoxin. The opposite situation, low CO2 and high NH3 (ammonia), will tend to cause an accumulation of these substances. Therefore, a simple metabolic shift that predictably happens in stress and malnutrition, can explain the main type of porphyria, independently of specific genetic problems. Everyone's genetic constitution is unique, and in a metabolically complex condition such as porphyria, there will be a spectrum of susceptibility. To draw a line across the spectrum, dividing people with "genetic defects" from the normal, is a purely arbitary and illogical procedure. It is much more important to identify and eliminate "porphyriogenic" environments.

Since porphyria attacks commonly occur premenstrually or after skipping a meal, the food cravings caused by increased estrogen and lowered blood sugar, are probably reinforced in many people by dread of the terrible symptoms that can be produced by not eating enough, resulting from the increased ammonia and porphyrins or porphyrin precursors. Calorie restriction can be dangerous when porphyria is developing.

The presence of porphyrin poisoning, with its associated free radical toxins, can lead to the activation of heme oxygenase, the enzyme which produces carbon monoxide, which I have discussed elsewhere as a cause of the respiratory defect that characterizes cancer. Both ammonia and porphyria have been implicated in the production of cancer.

Acetazolamide, a drug that causes carbon dioxide to be retained in the tissues, tends to block the formation of ammonia. This is probably a confirmation of the importance of carbon dioxide as an anti-ammonia factor. High altitude also causes increased retention of carbon dioxide in the tissues, because of the Haldane-Bohr effect,

and the reduction of ammonia (production, serum concentration, and excretion) at high altitude is probably even greater than the reduction of lactate production.

Fibrotic tissue can be repaired, and the essential thing is to interrupt the processes that caused it to develop. I have written previously about the effects of vitamin E, progesterone, and DHEA on scars, keloids, scleroderma, arthritis, and liver cirrhosis, but there are many helpful therapies. Saturated fats are extremely important in the reversal of fibrosis. Recently, it has been found that just covering a keloid with a layer of silicone causes it to regress to some extent. I think the sealant allows carbon dioxide to accumulate, shifting the balance away from growth and toward shrinkage of the collagenous mass.

The particular therapy that's most helpful will depend on the particular nature of the stressor, but good nutrition is always of the greatest importance. Carnitine protects against ammonia; adenosine, niacin, and caffeine protect against various types of excitotoxicity. Vitamin A protects against premature cornification, and probably other cross-linking. Thyroid, progesterone, and glucose help to minimize exaggerated protein catabolism, and magnesium has a great variety of restorative functions.

Carnitine has been used with sodium benzoate and phenylacetate to lower ammonia, but the latter can produce some side effects. Except for treating neurotoxic ammonia, I don't recommend use of carnitine supplementation, since there is good evidence that carnitine increases oxidative damage when there is an abundance of unsaturated fat in the organism. Aspirin's similarity to benzoate and phenylacetate suggests that it might sometimes help to remove ammonia. The safest procedure is to use foods, such as fruit juices, that regulate nitrogen metabolism in varied ways.

The alpha-keto acids, which are found in many fruits, can bind ammonia, becoming ordinary amino acids. Potato juice (eliminating the starch with a carrot juicer) is a rich source of these alpha-keto acids.

Estrogen increases fairly steadily with aging in men, and its effects become more harmful as testosterone and other protective antiestrogens decline with aging. In women, the absolute estrogen level rises until near menopause, but during those years very high levels of progesterone protect most women against its harmful effects. The diseases that affect women more often than men are mainly diseases caused by a failure of progesterone and thryoid to regulate estrogen. The generally greater resistance and longevity of women can be attributed largely to progesterone dominance over estrogen. The extremely high progesterone production during pregnancy probably has long lasting protective effects, since there is clear evidence that longevity increases with the number of children borne. In animals, a large number of pregnancies produces anti-aging, and anti-estrogenic, effects that can be seen even in the elasticity of tendons.

The amount of irradiation needed to extend the shelf life of food is around 100,000 rads to 300,000 rads or even more, and even that intensity can't overcome the problem of dirty production facilities. **This amount of radiation produces a large amount of ammonia in food.** Dogs fed meat that had been irradiated were found to have severely depressed essential amino acids, and a low level of magnesium, protein, and creatinine in the blood. Vitamin A and other nutrients were depleted.

been shown in vitro to be a turnover-dependent inactivator of peptidylglycine alpha-monooxygenase (PAM), the rate-limiting enzyme involved in the formation of amidated neuropeptides from their glycine-extended precursors. In the studies reported herein, we have shown that PBA produces a dose-dependent (50-500 mg/kg s.c.) inhibition of serum PAM activity in normal rats without affecting peptidylamidoglycolate lyase activity. Because amidated neuropeptides such as substance P and **calcitonin gene-related peptide are involved in acute inflammation, we evaluated the effects of PBA on carrageenan-induced inflammation in rats. The acute administration of PBA (s.c. or i.p.) produced a dose-related inhibition of edema with maximum inhibition (67%) observed at 2 hr postphlogistic agent. In addition, the continuous administration of PBA to animals over a 7-day period using osmotic pumps not only inhibited hind paw swelling induced by carrageenan but also inhibited serum PAM activity** and reduced tissue levels of substance P in hind paws. These results demonstrate for the first time a correlation between the antiinflammatory activity produced by an inhibitor of peptide amidation with its ability to inhibit serum PAM activity and lower endogenous tissue levels of substance P. Moreover, these results confirm our contention that PAM is an excellent pharmacological target for controlling the acute inflammatory response. We also demonstrate the ability of PBA to inhibit phenyl-p-quinone and acetylcholine-induced writhing in mice without affecting the spinally mediated tail immersion assay in rats. Because this analgesic effect was extremely rapid (within 15 min), PBA may be producing this effect by a mechanism other than peptide amidation.

MAIN IDEAS AND CONTEXTS

***Lactic acid and carbon dioxide** have opposing effects.*

***Intense exercise damages** cells in ways that cumulatively impair metabolism. There is clear evidence that glycolysis, producing lactic acid from glucose, has toxic effects, suppressing respiration and killing cells. Within five minutes, exercise lowers the activity of enzymes that oxidize glucose. Diabetes, Alzheimer's disease, and general aging involve increased lactic acid production and accumulated metabolic (mitochondrial) damage.*

***The products of glycolysis**, lactic acid and pyruvic acid, suppress oxidation of glucose.*

***Adaptation** to hypoxia or increased carbon dioxide limits the formation of lactic acid. Muscles are 50% more efficient in the adapted state; glucose, which forms more carbon dioxide than fat does when oxidized,, is metabolized more efficiently than fats, requiring less oxygen.*

***Lactic acidosis**, by suppressing oxidation of glucose, increases oxidation of fats, further suppressing glucose oxidation.*

***Estrogen** is harmful to mitochondria, **progesterone** is beneficial.*

***Progesterone's brain-protective** and restorative effects involve mitochondrial actions.*

***Thyroid hormone, palmitic acid, and light** activate a crucial respiratory enzyme, suppressing the formation of lactic acid. Palmitic acid occurs in coconut oil, and is formed naturally in animal tissues. Unsaturated oils have the opposite effect.*

***Heart failure, shock**, and other problems involving excess lactic acid can be treated "successfully" by poisoning glycolysis with dichloroacetic acid, reducing the production of lactic acid, increasing the oxidation of glucose, and increasing cellular ATP concentration. Thyroid, vitamin B1, biotin, etc., do the same.*

B1

Mitochondria and mortality: Diet, exercise, and medicine, damaging or repairing respiratory metabolism

Since reading Warburg's publications in the late 1960s and early 70s, and doing my own research on tissue respiration, I have been convinced that Warbug was on the right track in seeing mitochondrial respiration as the controlling influence in cell differentiation, and in seeing cancer as a reversion to a primitive form of life based on a "respiratory defect." Harry Rubin's studies of cells in culture have expanded Warburg's picture of the process of cancerization, showing that genetic changes occur only after the cells have been transformed into cancer.

It is now well recognized that defective mitochondrial respiration is a central factor in diseases of muscles, brain, liver, kidneys, and other organs. The common view has been that the mitochondrial defects are produced by genetic defects, that are either inherited or acquired, and are irreversible.

Mitochondria depend on some genes in the nuclear chromosomes, but they also contain some genes, and mutations in these specific mitochondrial genes have been associated with various diseases, and with aging. Although these aren't the genes that the cancer establishment has focussed on as "the cause" of cancer, for people interested in the achievements of Warburg and Rubin, it is important to know whether mutations in these mitochondrial genes are the *cause* of respiratory defects, or whether a respiratory defect causes the mutations. Recent research seems to show that physiological problems precede and cause the mutations.

Warburg believed that mitochondria supported specialized cell functions by concentrating themselves in the places where energy is needed. This idea has some interesting implications. For example, when the amount of thyroid hormone is increased, or when the organism adapts to a high altitude, the number of mitochondria increases. But in energy deficient states such as diabetes, they don't. How are these crucial organelles called into existence by the hormone that increases respiration and energy, and also by the hypoxic conditions of high altitudes? In both of these conditions, the availability of oxygen is limiting the ability to produce energy. In both conditions, carbon dioxide concentration in tissue is higher, in one case, because thyroid stimulates its production, in the other, because the Haldane effect limits its loss from the lungs.

SOME DEFINITIONS

Glycolysis: The conversion of glucose to lactic acid, providing some usable energy, but many times less than oxidation provides.

***Lactic acid,** produced by splitting glucose to pyruvic acid followed by its reduction, is associated with calcium uptake and nitric oxide production, depletes energy, contributing to cell death.*

***Crabtree effect:** Inhibition of cellular respiration by an excess of glucose; excess of glucose promotes calcium uptake by cells.*

***Pasteur effect:** Inhibition of glycolysis (fermentation) by oxygen.*

***Randle effect:** The inhibition of the oxidation of glucose by an excess of fatty acids. This lowers metabolic efficiency. Estrogen promotes this effect.*

***Lactated Ringer's solution:** A salt solution that has been used to increase blood volume in treating shock; the lactate was apparently chosen as a buffer in place of bicarbonate as a matter of convenience rather than physiology. This solution is toxic, partly because it contains the form of lactate produced by bacteria, but our own lactate, at higher concentrations, produces the same sorts of toxic effect, damaging mitochondria.*

***Estrogenic phytotoxins** damage mitochondria, kill brain cells; tofu is associated with dementia.*

Could carbon dioxide, a major product of mitochondria, help to call mitochondria into existence? My answer to this is "yes," and it will help to briefly explain how I see mitochondria. Although I have no hesitancy in accepting that organelles can be exchanged between species, and that it is conceivable that mitochondria might have been derived from symbiotic bacteria, I am reluctant to believe that something happens just because it *could* happen. For example, Francis Crick proposed that life on earth originated when genes arrived here on space dust from some other world. That's a theoretical possibility, but what's the point? It just avoids explaining how the highly organized material came into existence somewhere else, and it probably seriously interfered with the consideration of the ways life could arise here. Similarly, some people like to think that mitochondria and chloroplasts were originally bacteria, that came into symbiosis with another kind of living material, consisting of nucleus and cytoplasm. Like Crick's "space germs," it can be argued that it's possible, but the problem is that this explanation can stop people from thinking freshly about the nature of the various organelles, and how they came to exist. (How did cells originate? How did mitochondria originate? "Germs.")

Since I have a view of how cells came to exist, under conditions that exist on earth, I should consider whether that view doesn't also reasonably account for their various components. Sidney Fox's proteinoid microspheres provide a good model for the spontaneous formation of primitive cells; variations of that idea can account for the formation of organelles (such as mitochondria and nuclei within cells, and chromosomes within nuclei). The value of this idea, of a self-stimulating process in mitochondrial generation, is that it suggests many ways to test the idea experimentally, and it suggests explanations for developmental and pathological processes that otherwise would have no coherent explanation.

Proteinoid microspheres and coacervates form by acquiring molecules from solution, condensing them into a separate phase, with its own physical properties. At every phase boundary, there are numerous physical forces, especially electronic properties, that make each kind of interface different from other kinds. Small changes of pH, temperature, of salts and other solutes can alter the interfacial forces, causing particles to dissolve,

or grow, or fragment, or to move. In the way that carbon dioxide alters the shapes and electrical affinities of hemoglobin and other proteins, I propose that it increases the stability of the mitochondrial coacervate, causing it to "recruit" additional proteins from its external environment, as well as from its own synthetic machinery, to enlarge both its structure and its functions.

In the relative absence of carbon dioxide, or excess of alternative solutes and adsorbents, such as lactic acid, the stability of the mitochondrial phase would be decreased, and the mitochondria would be degraded in both structure and function. As the back side of the idea that carbon dioxide stabilizes and activates mitochondria, the idea that lactic acid is involved in the degrading of mitochondria can also be tested experimentally, and it is already supported by a considerable amount of circumstantial evidence.

This combination of sensitivity to the environment, with a kind of positive feedback or inertia either upward or downward, corresponds to what we actually see in mitochondrial physiology and pathology.

The Crabtree effect, which is the suppression of respiration by glycolysis, is often described as the simple opposite of the Pasteur effect, in which respiration limits glycolysis to the rate that allows its product to be consumed oxidatively. But the Pasteur effect is a normal sort of control system; when the Pasteur effect fails, as in cancer, there is glycolysis which is relatively independent of respiration, causing sugar to be consumed inefficiently. Embryonic tissues sometimes behave in this manner, leading to the suggestion that glycolysis is closely related to growth. Unlike the logical Pasteur effect, the Crabtree effect tends to lower cellular energy and adaptability. Looking at many situations in which increasing the glucose supply increases lactic acid production and suppresses respiration, leading to maladaptive decrease in cellular energy, I have begun thinking of lactic acid as a toxin. The use of Ringer's lactate solution in medicine has led many people to assume that lactate must be beneficial, or they wouldn't put it in the salt solution that is often used in emergiencies; however, I think its use here, as a buffer, is simply a convenience, because of the instability of some bicarbonate solutions.

On the organismic level, it is clear that lactic acid is "the essence of hyperventilation," and that it produces edema and malfunction on a grand scale: The panic reaction, shock lung, vascular leakiness, brain swelling, and finally multiple organ failure, all can be traced to an excess of lactic acid, and the related features of hyperventilated physiology.

Otto Warburg apparently thought of lactate as simply a sign of the respiratory defect that characterizes cancer. V. S. Shapot at least hinted at its possible role in turning on the catabolic reactions leading to cancer cachexia (wasting). I think a good case can be made for lactate as the *cause* of the respiratory defect in cancer, just as it is usually the immediate cause of the respiratory derangement of hyperventilation on the organismic level.

The Crabtree effect is usually thought of as just something that happens in tumors, and some tissues that are very active glycolytically, and some bacteria, when they are given large amounts of glucose. But when we consider lactate, which is produced by normal tissues when they are deprived of oxygen or are disturbed by a stress reaction, the Crabtree effect becomes a very general thing. The "respiratory defect" that we can see on the organismic level during hyperventilation, is very similar to the "systemic Crabtree effect" that happens during stress, in which respiration is shut down while glycolysis is activated. Since oxidative metabolism is many times more efficient for producing energy than glycolysis is, it is maladaptive to shut it down during stress.

Since the presence of lactate is so commonly considered to be a normal and adaptive response to stress, the shut-down of respiration in the presence of lactate is generally considered to be caused by something else, with lactate being seen as an effect rather than a cause. Nitric oxide and calcium excess have been identified as the main endogenous antirespiratory factors in stress, though free unsaturated fatty acids are clearly involved, too. However, glycolysis, and the products of glycolysis, lactate and pyruvate, have been found to have a causal role in the suppression of respiration; it is both a cause and a

consequence of the respiratory shutdown, though nitric oxide, calcium, and fatty acids are closely involved.

Since lactic acid is produced by the breakdown of glucose, a high level of lactate in the blood means that a large amount of sugar is being consumed; in response, the body mobilizes free fatty acids as an additional source of energy. An increase of free fatty acids suppresses the oxidation of glucose. (This is called the Randle effect, glucose-fatty acid cycle, substrate-competition cycle, etc.) Women, with higher estrogen and growth hormone, usually have more free fatty acids than men, and during exercise oxidize a higher proportion of fatty acids than men do. This fatty acid exposure "decreases glucose tolerance," and undoubtedly explains women's higher incidence of diabetes. While most fatty acids inhibit the oxidation of glucose without immediately inhibiting glycolysis, palmitic acid is unusual, in its inhibition of glycolysis and lactate production without inhibitng oxidation. I assume that this largely has to do with its important function in cardiolipin and cytochrome oxidase.

Exercise, like aging, obesity, and diabetes, increases the levels of circulating free fatty acids and lactate. But ordinary activity of an integral sort, activates the systems in an organized way, increasing carbon dioxide and circulation and efficiency. Different types of exercise have been identified as destructive or reparative to the mitochondria; "concentric" muscular work is said to be restorative to the mitochondria. As I understand it, this means contraction with a load, and relaxation without a load. The heart's contraction follows this principle, and this could explain the observation that heart mitochondria don't change in the course of ordinary aging.

When a person has an accident, or surgery, and goes into shock, the degree of lactic acidema is recognized as an indicator of the severity of the problem. Lactated Ringer's solution has been commonly used to treat these people, to restore their blood pressure. But when prompt treatment with lactated Ringer's solution has been compared with no early treatment at all, the patients who are not "rescuscitated" do better than those who got the early treatment. And when Ringer's lactate has been compared with various other solutions, synthetic starch solutions, synthetic hemoglobin polymer solution, or simply a concentrated solution of sodium chloride, those who received the lactate solution did least well. For example, of 8 animals treated with another solution, 8 survived, while among 8 treated with Ringer's lactate, 6 died.

Mitochondrial metabolism is now being seen as the basic problem in aging and several degenerative diseases. The tendency has been to see random genetic deterioration as the driving force behind mitochondrial aging. Genetic repair in mitochondria was assumed not to occur. However, recently two kinds of genetic repair have been demonstrated. One in which the DNA strand is repaired, and another, in which sound mitochondria are "recruited" to replace the defective, mutated, "old" mitochondria.

In ordinary nuclear chromosomal genes, DNA repair is well known. The other kind of repair, in which unmutated cells replace the genetically damaged cells, has been commonly observed in the skin of the face: During intense sun exposure, mutant cells accumulate; but after a period in which the skin hasn't been exposed to the damaging radiation, the skin is made up of healthy "young" cells.

In the way that the skin can be seen to recover from genetic damage, that had been considered to be permanent and cumulative, simply by avoiding the damaging factor, mitochondrial aging is coming to be seen as both avoidable and repairable.

The stressful conditions that physiologically harm mitochondria are now being seen as the probable cause for the mitochondrial genetic defects that accumulate with aging. Stressful exercise, which has been known to cause breakage of the nuclear chromosomes, is now seen to damage mitochondrial genes, too. Providing energy, while reducing stress, seems to be all it takes to reverse the accumulated mitochondrial genetic damage.

Fewer mitochondrial problems will be considered to be inherited, as we develop an integral view of the ways in which mitochondrial physiology is disrupted. Palmitic acid, which is a major

component of the cardiolipin which regulates the main respiratory enzyme, becomes displaced by polyunsaturated fats as aging progresses. Copper tends to be lost from this same enzyme system, and the state of the water is altered as the energetic processes change.

While the flow of carbon dioxide moves from the mitochondrion to the cytoplasm and beyond, tending to remove calcium from the mitochondrion and cell, the flow of lactate and other organic ions into the mitochondrion can produce calcium accumulation in the mitochondrion, during conditions in which carbon dioxide synthesis, and consequently urea synthesis, are depressed, and other synthetic processes are changed.

Glycolysis produces both pyruvate and lactate, and excessive pyruvate produces almost the same inhibitory effect as lactate; since the Crabtree effect involves nitric oxide and fatty acids as well as calcium, I think it is reasonable to look for the simplest sort of explanation, instead of trying to experimentally trace all the possible interactions of these substances; a simple physical competition between the products of glycolysis and carbon dioxide, for the binding sites, such as lysine, that would amount to a phase change in the mitochondrion. Glucose, and apparently glycolysis, are required for the production of nitric oxide, as for the accumulation of calcium, at least in some types of cell, and these coordinated changes, which lower energy production. could be produced by a reduction in carbon dioxide, in a physical change even more basic than the energy level represented by ATP The use of Krebs cycle substances in the synthesis of amino acids, and other products, would decrease the formation of CO2, creating a situation in which the system would have two possible states, one, the glycolytic stress state, and the other, the carbon dioxide producing energy-efficient state.

Besides the frequently discussed interactions of excessively accumulated iron with the unsaturated fatty acids, producing lipid peroxides and other toxins, the accumulated calcium very probably forms some insoluble soaps with the free fatty acids which are released even from intracellular fats during stress. The growth of new mitochondria probably occasionally leaves behind such useless materials, combining soaps, iron, and porphyrins remaining from damaged respiratory enzymes.

When the background of carbon dioxide is high, circulation and oxygenation tend to prevent the anaerobic glycolysis that produces toxic lactic acid, so that a given level of activity will be harmful or helpful, depending on the level of carbon dioxide being produced at rest.

Preventively, avoiding foods containing lactic acid, such as yogurt and sauerkraut, would be helpful, since bacterial lactic acid is much more toxic than the type that we form under stress. Avoiding the stress-promoting antithyroid unsaturated oils is extremely important. Their role in diabetes, cancer, and other age-related and degenerative diseases (and I think this includes the estrogen-promoted autoimmune diseases) is well established. Avoiding phytoestrogens and other things that increase estrogen exposure, such as protein deficiency, is important, because estrogen causes increased levels of free fatty acids, increases the tendency to metabolize them at the expense of glucose metabolism, increases the tissue content of unsaturated fatty acids, and inhibits thyroid functions.

Light promotes glucose oxidation, and is known to activate the key respiratory enzyme. Winter sickness (including lethargy and weight gain), and night stress, have to be included within the idea of the "respiratory defect," shifting to the antirespiratory production of lactic acid, and damaging the mitochondria.

Therapeutically, even powerful toxins that block the glycolytic enzymes can improve functions in a variety of organic disturbances "associated with" (caused by) excessive production of lactic acid. Unfortunately, the toxin that has become standard treatment for lactic acidosis--dichloroacetic acid--is a carcinogen, and eventually produces liver damage and acidosis. But several nontoxic therapies can do the same things: **Palmitate (formed from sugar under the influence of thyroid hormone, and found in coconut oil), vitamin B1, biotin, lipoic acid, carbon dioxide, thyroid, naloxone, acetazolamide, for example.** Progesterone, by blocking

estrogen's disruptive effects on the mitochondria, ranks along with thyroid and a diet free of polyunsaturate fats, for importance in mitochondrial maintenance.

Estrogen's Mechanisms in Aging and Cancer

Estrogen is an important factor in aging and cancer, but the fact of its toxicity is systematically obscured, discouraging proper treatments.

If we want to understand what estrogen is, we should know what it does, and how it does it. Despite the drug industry's weekly releases to the mass media, explaining the wonderful consequences of "selectively activating the estrogen receptor," it isn't clear what estrogen does. It is, however, perfectly clear that estrogen doesn't do the things the industry says it does.

The industry's basic story was that estrogen is "the female hormone," and that supplementing it makes all of the female functions better, including fertility and pregnancy.

But in reality, supplemental estrogen masculinizes, sterilizes, promotes prostate cancer, kills embryos and fetuses, breaks chromosomes, disorganizes cell division, mutates genes, causes seizures, and shifts metabolic patterns.

One of estrogen's relatively normal effects is to shift metabolism toward the production of more lactic acid, and less ATP. Examining these relatively simple effects offers very interesting insights into what estrogen is.

Changing the cell's energy economy through modulation of enzymes is an important alternative to special receptor-mediated actions. This approach is probably the only one that can account for the estrogenic actions of oxygen deprivation and irradiation with x-rays or ultraviolet rays.

The right food, the right activity, the right air and the right light, supported when necessary by the right hormone or drug, can change the basic energy metabolism.

The idea of "estrogen dominance" in menopause has been accepted by many people, but its application to therapy has been very limited. The ways in which nutrition and the thyroid hormone can lower estrogen production just aren't being discussed in the books that recognize the role of estrogen dominance in the menopause.

Gradually, a few people are recognizing that progesterone can be used for other situations in which estrogen causes sickness. The role of estrogen in epilepsy, depression, circulatory disorders, and migraine is starting to be recognized, because of the immediate effects of supplemental progesterone. But estrogen's role in emphysema, asthma, liver and gall-bladder disease, diabetes, arthritis, strokes, movement disorders, memory problems, multiple organ failure, and a variety of inflammatory conditions is being neglected, for reasons that are largely ideological.

In pregnancy, menstrual disorders, and menopause, the situation makes it easy to think of the sex hormones, and the idea of balancing two of them seems plausible. Katharina Dalton popularized the idea that the premenstrual disorder could be diagnosed by finding a monthly rhythm in the symptoms, and treated by taking progesterone premenstrually. That was an extremely important contribution, because it gradually made doctors realize that the "syndrome" wasn't just a matter of monthly water retention, as the journals had characterized it.

But when the sickness doesn't have a clear monthly rhythm, or isn't associated with menopause, or isn't cured by supplemental progesterone, or occurs in a man or child, estrogen's role can easily be overlooked. If a problem is caused by stress, or x-rays, or aging, or a genetic mutation, some people think estrogen and progesterone are irrelevant.

This is because of a medical culture and ideology. As long as that culture defines the issues, very simple approaches to "insoluble" health problems are going to be ignored.

If we learn to see the problems in terms of a general disorder of energy metabolism, we can begin to solve them.

A. The Issues

Before genes were known to be made of DNA, some people spoke of the nucleus as if it were the "brain of the cell," although many experiments showed that idea to be very misleading.

100 years ago the doctrine of Weismannism explained the development, from a single cell, of organisms with many different kinds of cell, by saying that all of the genes were contained in the first cell, but that as the fertilized egg divided, the genes were distributed, divided up so that each tissue received only the genes that it needed for its specific structure and function.

While this doctrine was in force, the development of tumors, which often produce cells with some of the characteristics of other tissues, was neatly explained as the growth of a fragment that was "displaced" during the embryo's growth: "an embryonal rest." Dermoid tumors or pilonidal cysts are still usually explained as displaced embryonic tissue. Many other things, especially aneurisms (some aneurisms, e.g., "berry aneurisms," resemble tumors), that appear at any point in life are commonly described as "congenital," because of the great and lingering influence of Weismannism, which held that developmental potential existed only in the "germ line" cells. These ideas persist in the medical culture because of the uncritical nature of medical training.

The doctrine, the culture, of Weismannism is behind the desire to say that the nucleus, with its genes, ***controls*** the cell.

The people who like to think that the "genes control the cell" have built their more modern understanding of human and mammalian biology on ideas that were developed in the 1950s and 1960s for explaining the responses of bacteria to different kinds of food. In bacteria, there is no distinction between nucleus and cytoplasm, and their DNA isn't arranged in chromosomes. Their appropriate adjustments to changes in their environment were explained in terms of regulatory molecules that activate and inhibit specific

"The results strongly suggest the possibility that all mRNAs may be expressed in a single human cell, of both somatic and germ lineage." *Y. Kimoto, 1998*

genes. (As I have mentioned before, the work of John Cairns [Cairns and Foster, 1991] and others has shown that there is something fundamentally wrong with this idea, even for explaining bacterial physiology.)

These ideas were applied to explaining the more complex processes that regulate cells that contain a nucleus. The gene-***discarding*** details of Weismannism were dropped, in favor of a new doctrine, in which genes were bound up and inactivated, except when they were specifically activated according to the specific needs of a tissue.

Hormone receptors were seen as analogs of the regulatory molecules in bacteria. The receptors that the drug companies talk about are almost always understood in terms of the bacterial regulatory model, in which a protein binds to a drug or a signal substance, and then moves into the nucleus where it binds to specific genes. (In this scheme, the hormone is said to be "providing information" to the cell, regulating the "information in the genes.")

In neurology, receptors have been used to explain why all nerves don't respond in the same way to molecules such as adrenaline, acetylcholine, and dopamine. During development certain of their genes were activated, producing the receptors that allow them to respond only to certain substances.

The two kinds of receptor belonged to two different cultures--endocrinologists simply believed that nerves didn't have estrogen receptors, and neurologists believed that the relevant gene expression was taken care of before birth. Both of these cultures have turned out to be radically mistaken.

Because of the idea that activation of genes by receptors had to explain everything, estrogen was said to act only through its "receptor protein," and for decades most biologists simply denied that estrogen could have essentially instantaneous effects on cells, the way nerve transmitters do. As hundreds of "impossible" facts piled up, the scientific/medical establishment bent a little, and decided that there was another estrogen receptor, which would account for the immediate actions of estrogen. The alpha and beta estrogen receptors are now familiar entities, if we believe what is being said by many medical endocrinologists.

But estrogen does many things, and some of them clearly don't involve either the "alpha" or "beta" receptor proteins. Rather than making it easier to understand all of estrogen's effects, another "receptor" is just another distraction, making it easier to ignore some of the unexplained facts.

What began as a reductionist attempt to explain everything in terms of chance and mechanistic materialism, has resulted in an infinite tangle of assumptions and wild interpretations.

What, specifically, is wrong with the idea that a hormone binds to and activates a receptor protein which then activates certain genes?

First, it has been asserted for more than 30 years that this is the only way a hormone can work. A few years ago, the single estrogen receptor was supplemented by another receptor. In mice which have been mutated to lack these receptors, there are still responses to estrogen, and so a "receptor X" has been proposed. As long as a cell or organism can respond to something, it will be claimed that there is a receptor for it.

Second, the "classical hormone receptor" idea claims that the receptor/response system is highly specific, and is activated by a highly specific binding of the hormone to the receptor, and of the complex to the gene.

Third, the doctrine claims to be so important that other processes of regulation and differentiation of cells are forgotten or treated as if they were trivial.

The first objection is really an objection to the medieval way of thinking, in which every reaction has to be reified, turned into a concrete object. This attitude seems to be useful in getting funding.

The second false claim has been amply disproved--the range of things which can activate estrogen receptors is great, and the evidence that falsifies the claim has existed longer than the identity of the estrogen molecule has been known.

The third point will be settled by anyone who investigates the massive amount of research demonstrating that cell physiology and structure are thoroughly dependent on processes that occur after the genes have produced their product, messenger RNA. The stabilization and degradation of the RNA, and its rearrangement and splicing, are clearly very closely connected with the cell's nature and function.

There might turn out to be many interesting "repressors" and "activators" of specific genes, that conform to the standard bacterial model, but that hasn't been what the drug industry wants us to believe. They have an interest in selling the idea that hormones and drugs have a specific ability to "unlock" certain genes. Estrogen might no longer unlock the "femininity genes," but it is supposed to unlock the genes that protect the bones, heart, and brain. The "estrogen receptor" no longer has anything at all to do with femininity. It is found in every organ of both men and women. When a mutant mouse was produced that lacked an estrogen receptor, testicular edema was one of the most noticeable problems. (There might be reason to think this indicates an *increased* activity of estrogen in the absence of the receptor: See Sowerbutts, et al., 1986).

The conversion of estrogen, in the early 1960s, from something that "increased fertility" to something that prevents fertility, started a process that convinced the industry that they should concentrate their sales effort on women who are already infertile. That probably saved the industry from extinction, since the use of estrogen during pregnancy caused not only miscarriages, but also birth defects and cancer and other diseases in the children. But the present claims that estrogen activates specific genes that protect the aging tissues will eventually sound as foolish as the idea of "femininity genes" does now.

Without the receptor doctrine, the introduction of new drugs might require evidence of actual health benefits.

The facts of hormonal control of cell function are much more interesting than the simple receptor dogma.

B. Some Evidence

Within the last few years, a new technique (reverse transcriptase-polymer chain reaction) has made it possible to detect very small amounts of RNA, to show in a very clear way whether certain genes in a single cell are active.

Y. Kimoto has applied the test to several very different types of cell. Some genes involved in energy production and the basic maintenance systems are known to be active in all sorts of cells, but other genes, such as those that are responsible for the highly specialized functions of mature tissues, are believed to be inoperative in tissues with a different kind of specialization. He showed that all of the 25 types of RNA, for making very different kinds of protein, were present in each type of cell. ***"These findings strongly suggest that every cell can express every mRNA. Beneath the cell differentiation there may exist a DNA-->RNA basal constant flow...."***

If all of the organism's genes are always active in every cell, then the question is clearly "what really governs the cell's differentiation, and the varying expression of the genes' protein products?"

When a cell doesn't need a particular kind of RNA, it is degraded almost instantly. When it is pressured to adapt in a certain direction, the RNA for making the adaptive proteins becomes very stable, and accumulates.

A similar process occurs with proteins, degrading them quickly, or protecting them. In many enzymes, a vitamin or other coenzyme binds to the protein and stabilizes it.

If the enzymic activity is changed in the presence of a hormone, many people have assumed that new proteins with different functions were produced by activation of genes, but in many cases, hormones (like vitamins) directly alter the functions of enzymes.

In the 1960s, Engel and his collaborators showed that estrogen binds to several enzymes, and that the association of estrogen with the enzyme alters the cell's chemistry, including the balance between oxidation and reduction. These enzymes could very properly be called "estrogen receptors," because they mediate the cell's response to estrogen. But the general atmosphere was such that only receptors which moved into the nucleus and bound to a gene could be accepted. Everything had to be explained by the prestigious bacterial model.

Nevertheless, in the 1960s and earlier there were other people who could demonstrate that basic changes in the cell's chemistry altered the expression of genes. C.D. Cone, Jr., showed that osmotic forces and the cell's surface electrical potential, which he manipulated by adjusting the ratio of sodium to potassium, could powerfully activate the genes. He demonstrated that even the nuclei of brain cells could be stimulated to undergo mitosis, duplicating their DNA as a result of a simple change of the salt balance.

Around 1985, stress (high temperature, or deprivation of oxygen or glucose, for example) was found to alter gene expression in a systematic way. **It turned out that estrogen activates these same "stress proteins."**

This was particularly interesting, since many years earlier it was demonstrated that many kinds of stress imitated the function of estrogen. Suffocation or x-ray exposure (of the brain, or ovary, or any part of the body) would trigger the lordosis reaction, for example. More recently, it has been noticed that a moderate x-ray exposure of the brain can bring on premature puberty in girls. And irradiation (x-rays, gamma rays, or ultraviolet rays) synergizes in other ways with estrogen, for example in causing cancer.

The estrogen receptor, even without any estrogen, will still move into the nucleus and bind to the genes, under the stress of oxygen deprivation. This is consistent with the idea that estrogen is doing something to the cell that resembles the changes produced by the other stressors. Under more objective circumstances, the "estrogen receptor" might have been identified as just another of the components in a stress response.

Heat shock can increase the number of estrogen receptors (Marin, et al., 2001). Estrogen, too, generally increases the quantity of the estrogen receptor protein.

Testosterone, thyroid, cortisone are known to stabilize certain RNAs, causing the expression of gene products without necessarily doing anything directly to the gene. The overwhelming emphasis in research now seems to be on the factors that regulate the stability of RNA, rather than on the simpler bacterial model of gene activation.

In 1996, many people spoke of the original estrogen receptor as if it moved "from the membrane" through the cytoplasm to the nucleus, because of a habit of thinking of the cell surface as a "membranous barrier." But the protein that they identified as their estrogen receptor was in the cytoplasm.

For more than 30 years, people had been noticing that estrogen had many effects that were practically instantaneous, for example causing cells to take up water and alter their electrical behavor. Cone's work demonstrated that the cell's water content and electrical behavior could activate the nucleus, so I didn't see the need for having separate explanations for regulating water, ions, electrical potentials, and genetic expression.

But the Other Major Dogma of cell biology has been that "the plasma membrane" regulates everything. When people heard about estrogen's or progesterone's or the thyroid hormone's instantaneous actions, they thought it must be a membrane-controlled response.

V.D. Ramirez and his collaborators began talking about the reality of a second estrogen receptor, the beta receptor, or membrane-associated receptor. (The original "gene activating receptor" has now become the alpha receptor.)

Their definition of "membrane" was very standard: First you homogenize the tissue, and then centrifuge it, and certain layers of the sludge are called membranes. That's because of the tradition in which membranes served to enclose the "watery" cytoplasm, so naturally they were the part that wasn't watery, i.e., they were the insoluble lump left after homogenization and centrifugation.

But they identified several proteins that estrogen stuck to: **ATPase (regulating energy and salt and water), and GAPDH, the rate controlling enzyme of glycolysis. Estrogen activates this enzyme, and physiologically estrogen activates the glycolytic pathway, increasing the production of lactic acid as it shifts metabolism away from mitochondrial oxidation, lowering the cell's ATP production, and shifts the use of oxygen functions, such as producing nitric oxide, the free radical which is a common mediator for all the harmful forms of radiation, and for oxygen deprivation.**

This particular enzyme interests me, because of its function in controlling glycolysis, but also because it is inactivated by cold, along with other important enzymes involved in the estrogen reaction. In 1971 I proposed that estrogen activated this enzyme by altering the "structural temperature" of the cell water, something which paralleled C.D. Cone, Jr.'s sodium/electrical effects, that is, it would be a holistic shift in the way the insoluble ("membrane") proteins behaved, making them more insoluble or hydrophobic.

But Ramirez's group, like Engel's, was suggesting that the binding of estrogen to the enzymes, changing their activity, was the regulatory principle, which doesn't make too much difference, since the various interpretations end up causing the same metabolic shifts, toward the metabolism of stress, or cancer, or estrogen dominance. The shift of metabolism toward lactic acid production and lower energy production will also cause some holistic changes, such as changing the redox balance, possibly increasing the pH, and lowering the energy charge. However, I think a change in the cell's hydrophobicity or structural temperature would also make coherent changes in the stability of RNA as well as of proteins.

The activation of the other enzyme, ATPase, in Ramirez's experiments, is even more supportive of the idea that estrogen is modifying the cell water, lowering its order the way increased temperature would. In the mitochondrion, the enzyme that synthesizes ATP (ATP synthetase) will also destroy ATP, if conditions are changed.

The three main conditions that cause the enzyme to destroy ATP are prolonged standing after separating the mitochondria from the cells, freezing the mitochondria and then slowly thawing them (messing them up more thoroughly than when they are rapidly thawed), and treating them with estrogen.

Destroying the cell's ATP at a high rate is an important factor in forcing the cell to get its energy from glycolysis, producing lactic acid.

All of the stages involved in the development of cancer are promoted by estrogen. For example, the local acidification produced by lactic acid production promotes invasiveness, by activating proteolytic enzymes.

The mere presence of lactic acid in the blood displaces carbon dioxide, with many harmful consquences (all of which are seen in the estrogen dominant state). Carbon dioxide is in effect our basic protection against free radical damage. (Boljevic, et al., 1996.) Carbon dioxide is generally thought to be a major factor in regulating the balance of water in the body. For example, hyperventilation increases capillary leakiness, and causes fluid to leak out into the tissues. Estrogen decreases carbon dioxide by causing hyperventilation and increased lactic acid production. **Estrogen systemically increases capillary leakiness.** (Cho, et al., 1999; Ziylan, et al., 1990; Reid, et al., 1983; Merlen, 1982.) **The capillary leakiness is corrected by progesterone.** (Lagrue, et al., 1983.)

The idea that estrogen increases the structural temperature of cell water, even while the real temperature might be decreasing, would be consistent with the fact that the "heat shock" or stress proteins are expressed under estrogen's influence. And when, under the influence of estrogen or the unsaturated fatty acids, cells take up more water, they also take up a little sodium. This reduces the organizing influence of the cell's proteins on the water, and this is what increases its structural temperature. When the nervous system, responding to estrogen, "sets the thermostate lower," there is a slight restoration of the cell's water and protein interactions, but metabolic processes are slowed at the lower temperature.

Estrogen, like radiation and oxygen deprivation, increases formation of the nitric oxide (NO) free radical, which has so many harmful effects, ranging from damaging DNA to poisoning mitochondria. One of the consequences of increasing NO formation (and estrogen) is the activation of an enzyme (heme oxygenase) which produces carbon monoxide, in the process of breaking down the heme molecule (which is needed for respiratory enzymes, among other essential functions). In previous newsletters I have discussed the reasons for thinking that endogenously produced carbon monoxide could explain the gradual development of cancer, since it stabilizes cells in the primitive anti-respiratory condition.

Any injury that an organism can survive is likely to activate the defensive systems, increasing the organism's ability to survive a subsequent stress (e.g., Meerson, et al., 1991), and this seems to explain why estrogen treatment sometimes has a protective effect. In a healthy menstrual cycle, estrogen's dominance is present for just a few hours, and this short stimulus serves to stimulate compensatory production of progesterone. Ever since Lipshutz's experiments in the 1940s, it has been known that it is the prolonged, uninterrupted action of estrogen that is profoundly harmful, not the brief cyclical exposures.

It's the prolonged shock-like state that contributes to the degenerative diseases, which typically begin with a sort of diabetes, an inability to use glucose for energy because of the accumulation of too much of the wrong kind of fat.

C. Protective Measures

The avoidance of stress is the basic principle for preventing the development of the estrogen-dominant state. Since darkness is itself a stress, generally increased exposure to strong light that is rich in the long-wave part of the spectrum, yellow to red, is protective, since these frequencies restore enzymes damaged by stress. Avoiding ionizing radiation whenever possible is very important, and this includes especially medical/dental x-rays, which are almost always unnecessary.

The polyunsaturated fats, toxic heavy metals, and inappropriate amounts of certain amino acids, such as tryptophan, cysteine, leucine, and

glutamate, increase our sensitivity to stress of all sorts, including radiation, and so should be avoided as far as possible. Coconut oil or palm kernel oil (which is even more saturated than coconut oil, with a generous supply of the short fatty acids) should be used regularly, since it isn't possible to avoid the toxic unsaturated fats entirely. (Generally, starchy food should be avoided, for several reasons: Persorption, obesity, and the nature of the foods that contain them.)

Many drugs that are currently popular decrease stress resistance. A few drugs are protective in the short term, but are toxic if used for a long time. Aspirin protects against some of the worst stressors, including the polyunsaturated fats, so despite its mild toxicity, long term studies usually show that it decreases sickness and mortality. Antibiotics, though they are toxic in themselves, also have powerful antistress effects.

In stress, magnesium and sodium are lost rapidly, so the diet should contain foods such as fruits and meats that contain significant amounts of magnesium. Added sodium helps to spare magnesium.

Occasional use of liver, to assure a generous supply of vitamins and trace minerals, is safer than using chemical supplements. Niacin and thiamine help to correct some of the metabolic distortions created by stress or estrogen.

The specifically antiestrogenic hormones, thyroid (especially T3), pregnenolone, and progesterone, can compensate to some extent for exposure to any of the stressors, including ionizing radiation.

Proteins corresponding to the mRNA investigated were mucin antigen, melanoma antigen, pregnancy-specific beta-1 glycoprotein 4, phenylethanolamine-N-methyl-transferase, beta B3-crystallin, homeobox 4A, interleukin 2, cluster of differentiation 8, progesterone receptor, parathyroid hormone, gastrin, cholecystokinin/pancreozymin, **glucagon, insulin, enkephalin, thyroid stimulating hormone, adrenocorticotropic hormone, synapsin I,** immunoglobulin (Ig)M, IgD, IgG1, IgG3, IgE, IgA, and T cell receptor alpha. All mRNAs were detected in single lymphocytes of two individuals, without exception. **In addition, transcripts of IgM, IgD, IgG1, IgG3, IgE, IgA, and the T cell receptor a gene were detected in single sperms.** The results strongly suggest the possibility that all mRNAs may be expressed in a single human cell, of both somatic and germ lineage. Thus, cells can consume energy in vain to produce functionally meaningless gene transcripts. However, this basal or illegitimate transcription may be essential for the birth of living matter: the arrow of time in a cell. Moreover, the phenomenon implies the potential of using lymphocytes in place of inaccessible tissue for the diagnosis of genetic diseases.

Genes Chromosomes Cancer 1998 May;22(1):83-6. **Expression of heavy-chain constant region of immunoglobulin and T-cell receptor gene transcripts in human non-hematopoietic tumor cell lines.** Kimoto Y. Expression of gene transcripts for immunoglobulins and a T-cell receptor was investigated in non-hematopoietic tumor cell lines using the highly sensitive RT-nested PCR method. These proteins are reported to be produced and secreted or expressed in malignancies originating from hematopoietic organs only. Originally designed PCR primers for different exons coding for the heavy-chain constant regions of IgM, IgD, IgG3, IgG1, IgE, and IgA and the T-cell receptor-alpha were used. All gene transcripts were detected in the 5 investigated cancer cell lines without exception. The results suggest that even non-hematopoietic cancer cells transcribe immunoglobulin and T-cell receptor genes and may produce the corresponding proteins.

Hum Cell 1996 Dec;9(4):367-70. **A possibility of all mRNA expression in a human single lymphocyte.** Kimoto Y. Expression of gene transcripts for 16 proteins was investigated in a human single lymphocyte using RT-nested PCR method. Examined mRNAs were for IL-2, CD8, progesterone receptor, parathyroid hormone, gastrin, glucagon, cholecystokinin/pancreozymin, insulin, enkephalin, thyroid stimulating hormone, MUC1, MAGE1, pregnancy-specific beta-1 glycoprotein 4, phenylethanolamine-N-methyltransferase, beta B3-crystallin and HOX4A. Most of the proteins were thought to be functionally irrelevant to a lymphocyte. All of them were detected in a lymphocyte without exception. The result suggests that there is a possibility of all mRNA expression in a human single cell

Hum Cell 1995 Dec;8(4):202-10. **Gene transcripts of eleven proteins with specific functions are all detected in human normal cells and tumor cell lines: a possible DNA-->RNA basal constant flow.** Kimoto Y.

Growth hormone: Hormone of Stress, Aging, & Death?

The name "growth hormone" is misleading; stress produces somatic growth, in a process called "hormesis." Exercise produces muscle edema, to a degree similar to that produced by GH; edema stimulates growth, but GH effect isn't limited to bone and muscle.

Identity of GH: Molecular ambiguity, complex modifications change one substance into many; its evolution suggests a role in water regulation. Doctrine of a "specific molecule" and "specific receptor" and specific effects is a myth.

The osmoregulatory problem--keeping water under control--is centrally involved in stress.

In mammals, the kidneys and bowel are the main regulators of water balance.

GH is a stress hormone. Its effects can be produced osmotically, for example inducing milk production and cartilage growth, by osmotic (dilution) shock.

Estrogen produces increased GH, and increases its production in stress.

Nitric oxide is a pro-aging free radical induced by estrogen, releasing GH; all three produce edema.

Behind edema, hypoxia, hypocarbia; free fatty acids, diabetes, vascular leakiness, degenerative kidney changes, connective tissue changes, thickened basement membrane, retinal degeneration. The same changes occur in aging: increased permeability; kidney disease, connective tissue changes.

The absence of GH protects kidneys against degeneration. Osteoarthritis, a characteristic aging condition, is caused by estrogen and GH.

Some studies found that heart failure and bone repair aren't improved by GH; GH is very high during heart failure, in which edema contributes to the problem; carpal tunnel syndrome, myalgia, tumor growth, gynecomastia, and many other problems have been produced by GH treatments.

Recently I heard Robert Sapolsky interviewed, and he was describing the changes that prepare the body for short-term stress. He said the energy-mobilizing hormones, adrenalin and cortisol, increase, while the hormones that don't contribute to meeting the immediate problem, including the sex hormones and growth hormone, are suppressed, to save energy; growth and reproductive processes can be suspended for the few minutes of acute stress, to make the body more able to meet its acute needs. He reiterated: Growth hormone is suppressed by stress.

Sapolsky has done very interesting work on the suppression of testosterone by stress, and on the way in which brain cells are killed by prolonged exposure to glucocorticoids. He showed that if extra glucose is supplied, the brain cells can survive their exposure to cortisol. In the body, adrenalin and the glucocorticoids increase the availability of glucose.

In the radio interview, he didn't have time for much detail, but it seemed to me that he wasn't talking about the same growth hormone that I have been reading about, and trying to understand, for years. Since people have asked me to write about the current anti-aging uses of GH, and its use in the dairy industry, Sapolsky's statements made me decide to think about some of the issues around the hormone.*

Bovine Growth Hormone is used to make cows give more milk.

Human Growth Hormone is supposed to make men lean and muscular, not to increase their milk production.

The "growth hormone" was named long before it was actually found, and the substance with that name turns out to be involved in many

processes other than growth. It is being given to cows to make them produce more milk, and it is being given to people with the purpose of making them lean and muscular, and with the hope of building stronger bones.

It isn't surprising that the Growth Hormone helps breasts develop and promotes milk production, since it is very similar to prolactin. GH and prolactin are members of a family of proteins that have diverged from each other in evolution, but they still have many overlapping effects.

When GH is treated as a drug, it is supposed to have a discrete identity, based on the sequence of its amino acids. But the natural hormone (disregarding the existence of a variety of closely related peptide with slightly different amino acid composition) varies with time, being chemically modified even before it is secreted. For example, its acidic amino acids may be methylated, and its lysine groups may combine with sugars or carbon dioxide. **The *history* of the protein in the body determines its exact structure, and therefore its biological effects.**

Male animals secrete GH in pulses, but females secrete it more steadily. This pattern of secretion "masculinizes" or "feminizes" the liver (and other organs), determining the pattern of enzyme activity. It would be possible (though very difficult) to arrange a system for delivering doses in a pulsed, intermittent manner. In cows, this apparently isn't necessary, since the purpose of the growth hormone is presumably to "feminize" the milk-producing system. But the normal pattern of secretion is much more complex than simply being "pulsed" or "continuous," since it, like prolactin secretion, is responsive to changes in thyroid, estrogen, diet, stress, and many other factors.

**If Sapolsky had been talking about just mice and rats, his statement would have been generally accurate. Adrenaline stimulates rat pituitary cells to secrete GH, and since both increase the amount of free circulating fatty acids, it could be that rats' GH is suppressed by a fatty acid excess.*

For example, hormones in this family are, as far back in evolution as they have been studied, involved in the regulation of water and minerals. It is well established that increased water (hypotonicity) stimulates prolactin, and increased sodium inhibits its secretion. Growth hormone is also closely involved with the regulation of water and salts.

One of the best known metabolic effects of GH is that, like adrenalin, it mobilizes fatty acids from storage. GH is known to antagonize insulin, and one of the ways it does this is simply by the ability of increased free fatty acids to block the oxidation of glucose. At puberty, the increased GH creates a mild degree of diabetes-like insulin resistance, which tends to increase progressively with age.

In his book, *Why Zebras Don't Get Ulcers,* Sapolsky acknowledges some situations in which GH is increased by stress in humans, but I think he misses the real ways in which it operates in stress. One of the interesting features of cortisol, which Sapolsky showed killed brain cells by making them unable to use glucose efficiently, is that it makes cells take up unsaturated fatty acids more easily, interfering with their energy production. Since growth hormone also has this kind of "diatebetogenic" action, it might be desirable to suppress its secretion during stress, **but in fact, there are several kinds of stress that clearly increase its secretion, and in animals as different as fish, frogs, cows, and people it can be seen to play roles in water and salt regulation, growth and development, stress, and starvation.**

Heat, hypoglycemia, running, and some types of shock are known to stimulate growth hormone secretion, sometimes to levels ten or twenty times higher than normal. (Two kinds of stress that usually don't increase GH are cold and stimulus-deprivation.) I consider the growth hormone to be, almost as much as prolactin, a stress-inducible hormone. That's why I reasoned that, if an endocrinologist as good as Sapolsky can misunderstand GH to that degree, the public is even more likely to misunderstand the nature of the material, and to believe that it somehow acts *just on muscle, fat, and bones.*

And the normally functioning pituitary appears to be unnecessary to grow to normal height. (Kageyama, et al., 1998.)

W. D. Denckla discovered that the pituitary hormones are in some way able to accelerate the process of aging. They block the actions of thyroid hormone, decreasing the ability to consume oxygen and produce energy. The diabetes-like state that sets in at puberty involves the relative inability to metabolize glucose, which is an oxygen-efficient energy source, and a shift to fat oxidation, in which more free radicals are produced, and in which mitochondrial function is depressed. Diabetics, even though it is supposedly an inability of their cells to absorb glucose that defines their disease, habitually ***waste glucose, producing lactic acid*** even when they aren't "stressed" or exerting themselves enough to account for this seemingly anaerobic metabolism. It was noticing phenomena of this sort, occurring in a great variety of animal species, in different phyla, that led Denckla to search for what he called DECO (decreasing consumption of oxygen) or "the death hormone." (Vladimir Dilman noticed a similar cluster of events, but he consistently interpreted everything in terms of a great genetic program, and he offered no solution beyond a mechanistic treatment of the symptoms.)

Simply increasing the amount of free fatty acids in the blood will act like DECO or "the death hormone," but growth hormone has more specific metabolic effects than simply increasing our cells' exposure to fatty acids. The hormone creates a bias toward oxidizing of the most unsaturated fatty acids (Clejan and Schulz), in a process that appears to specifically waste energy.

Growth hormone plays an important role in puberty, influencing ovarian function, for example.

Removing animals' pituitaries, Denckla found that their aging was drastically slowed. He tried to isolate the death hormone from pituitary extracts. He concluded that it wasn't prolactin, although prolactin had some of its properties. In the last publication of his that I know of on that subject, he reported that he was unable to isolate the death hormone, but that it was "in the prolactin fraction." Since rats have at least 14 different peptides in their prolactin family, not counting the multitude of modifications that can occur depending on the exact conditions of secretion, it isn't surprising that isolating a single factor with exactly the properties of the chronically functioning aging pituitary hasn't been successful.

Denckla's experiments are reminiscent of many others that have identified changes in pituitary function as driving forces in aging and degenerative diseases.

Menopause, for example, is the result of overactivity of the pituitary gonatropins, resulting from the cumulatively toxic effects of estrogen in the hypothalamus.

A. V. Everitt, in his book on the hypothalamus and pituitary in aging, reported on studies in which **estrogen caused connective tissues to lose their elasticity, and in which progesterone seemed to be an antiestrogenic longevity factor.** Later, he did a series of experiments that were very similar to Denckla's, in which removal of the pituitary slowed the aging process. Several of his experiments strongly pointed to the prolactin-growth hormone family as the aging factors. Removal of the pituitary caused retardation of aging similar to food restriction. These pituitary hormones, especially prolactin, are very responsive to food intake, and the growth hormone is involved in the connective tissue and kidney changes that occur in diabetes and aging.

A mutant dwarf mouse, called "little," has only 5% to 10% as much growth hormone as normal mice, and it has an abnormally long lifespan.

Many experiments show that prolactin and estrogen have synergistic effects in causing tissue degeneration, including cancerization, and that their effects tend to operate with fewer protective restraining influences in old age. Estrogen stimulates both prolactin and growth hormone secretion. Thirty years ago, people were warning that estrogen contraceptives might produce diabetes, because they caused chronic elevation of growth hormone and free fatty acids.

Since estrogen causes a slight tendency to retain water while losing sodium, producing hypotonic body fluids, and since hypotonicity is a sufficient stimulus to cause prolactin secretion, I

have proposed that it is estrogen's effect on the body fluids which causes it to stimulate prolactin. In pregnancy, the fetus is exposed to fluids more hypotonic than can be accounted for by estrogen and prolactin alone; since GH lowers the salt concentration of fish when they enter the ocean from freshwater, it seems to be a candidate for this effect in pregnancy.

Growth itself is an intrinsic property of all cells, but the growth hormone does have its greatest influence on certain tissues, especially cartilage. Gigantism and acromegaly were what originally made people interested in looking for a growth hormone, and these are characterized by continued, exaggerated enlargement of bones and cartilage. In old age, cartilaginous structures such as the bones and ears keep enlarging. The fact that simply diluting the culture medium is sufficient to stimulate the growth of cartilage suggests that the growth hormone might be acting by its effects on water metabolism. **In fish which enter fresh water from the ocean, pituitary hormones of this family help them to balance salts in this new environment, but in the process, they develop osteoporosis and skeletal deformity, of the sort that occur more gradually in other animals with aging.**

Growth hormone clearly causes edema, and this is probably involved in the pathological processes that it can produce. The expansion of extracellular water has been reported, but others have concluded that the increased weight of muscles following GH treatment must be the result of "growth," **"because microscopic examination didn't show edema."** Statements of that sort give incompetence a bad name, because any student of biology or biochemistry has to know, before he does almost any experiment, that the way to determine the water content of a tissue is to compare the wet weight to the weight after thorough drying. Looking for water under a microscope is the sort of thing they do at drug companies to pretend that they have done something.

Estrogen, growth hormone, and nitric oxide, which tend to work as a system, along with free fatty acids, all increase the permeability of blood vessels. The leaking of albumin into the urine, which is characteristic of diabetes, is promoted by GH. In diabetes and GH treatment, the basement membrane, the jelly-like material that forms a foundation for capillary cells, is thickened. The reason for this isn't known, but it could be a compensatory"anti-leak" response tending to reduce the leakage of proteins and fats.

Besides being involved in kidney degeneration, vascular leakiness contributes to brain edema, and probably contributes to the "autoimmune" diseases.

Whatever the exact mechanism may be, it is clearly established that GH contributes to kidney degereration, **and the lack of GH, even the removal of the pituitary, is protective against kidney degeneration.**

Denckla's and Everitt's experiments can be interpreted much more clearly now that GH's essential contribution to kidney degeneration is known. Growth Hormone may not be precisely the Death Hormone that Denckla was looking for, but it is very close to it. **Anti-thyroid effects have been seen, and possibly even anti-growth effects during gestation, and in kidney disease. In newborns, high GH is associated with smaller size and slower growth;** in one study, this was associated wtith rapid breathing, presumably hyperventilation which is associated with stress. The shift to the diabetes-like fatty acid oxidation would be expected to inhibit respiration, and the chronic elevation of serum free fatty acids will have a generalized antithyroid effect. **Under the influence of GH, the proportion of unsaturated fatty acids is increased, as occurs under the influence of estrogen.**

Growth hormone blocks gonadotropin-stimulated progesterone production, and this could also affect thyroid and respiratory metabolism.

The increase of GH during sleep might seem to be utterly incompatible with the idea that it is a stress hormone, but in fact the other stress hormones, adrenalin, cortisol, and prolactin also tend to increase during night-time sleep. Thyroid function and progesterone function decrease at night. As I have argued previously darkness is one of our major stressors. Considering GH's tendency to cause edema, tissue swelling, it could

play a role in the nocturnal increase of the viscosity of blood, as the volume of blood is decreased by the leakage of fluid into the tissues. Another process with potentially deadly results that increase withaging and stress, is the passage of bacteria from the intestine into the blood stream; this process is increased under the influence of GH.

Acute, short term studies definitely show growth hormone to be a stress hormone with some destabilizing effects. Over a lifetime, it is possible that such things as chronically increased levels of unsaturated fatty acids in the blood, and increased leakiness of the blood vessels, could cumulatively produce the effects that Denckla ascribed to the Death Hormone.

J Clin Endocrinol Metab 1991 Apr;72(4):768-72 Expansion of extracellular volume and suppression of atrial natriuretic peptide after growth hormone administration in normal man. Moller J, Jorgensen JO, Moller N, Hansen KW, Pedersen EB, Christiansen JS University Department of Endocrinology and Internal Medicine, Aarhus Kommunehospital, Denmark. **Sodium retention and symptoms and signs of fluid retention are commonly recorded during GH administration in both GH-deficient patients and normal subjects. Most reports have however, been casuistic or uncontrolled. In a randomized double blind placebo-controlled cross-over study we therefore examined the effect of 14-day GH administration (12 IU sc at 2000 h) on plasma volume, extracellular volume (ECV), atrial natriuretic peptide (ANP), arginine vasopressin, and the renin angiotensin system in eight healthy adult men. A significant GH induced increase in serum insulin growth factor I was observed. GH caused a significant increase in ECV (L): 20.45 +/- 0.45 (GH), 19.53 +/- 0.48 (placebo) (P less than 0.01), whereas plasma volume (L) remained unchanged 3.92** +/- 0.16 (GH), 4.02 +/- 0.13 (placebo). A significant decrease in plasma ANP (pmol/L) after GH administration was observed: 2.28 +/- 0.54 (GH), 3.16 +/- 0.53 (placebo) P less than 0.01. Plasma aldosterone (pmol/L): 129 +/- 14 (GH), 89 +/- 17 (placebo), P = 0.08, and plasma angiotensin II (pmol/L) levels: 18 +/- 12 (GH), 14 +/- 7 (placebo), P = 0.21, were not significantly elevated. No changes in plasma arginine vasopressin occurred (1.86 +/- 0.05 pmol/L vs. 1.90 +/- 0.05, P = 0.33). Serum sodium and blood pressure remained unaffected. Moderate complaints, which could be ascribed to water retention, were recorded in four subjects [periorbital edema (n = 3), acral paraesthesia (n = 2) and light articular pain (n = 1)]. The symptoms were most pronounced after 2-3 days of treatment and diminished at the end of the period. In summary, 14 days of high dose GH administration caused a significant increase in ECV and a significant suppression of ANP.

Circulation 1991 Jun;83(6):1880-7. Pathogenesis of edema in constrictive pericarditis. Studies of body water and sodium, renal function, hemodynamics, and plasma hormones before and after pericardiectomy. Anand IS, Ferrari R, Kalra GS, Wahi PL, Poole-Wilson PA, Harris PC. "BACKGROUND. The pathogenesis of sodium and water accumulation in chronic constrictive pericarditis is not well understood and may differ from that in patients with chronic congestive heart failure due to myocardial disease. This study was undertaken to investigate some of the mechanisms. METHODS AND RESULTS. Using standard techniques, the hemodynamics, water and electrolyte spaces, renal function, and plasma concentrations of hormones were measured in 16 patients with untreated constrictive pericarditis and were measured again in eight patients after pericardiectomy. The average hemodynamic measurements were as follows: cardiac output, 1.98 l/min/m2; right atrial pressure, 22.9 mm Hg; pulmonary wedge pressure, 24.2 mm Hg; and mean pulmonary artery pressure **30.2 mm Hg. The systemic and pulmonary vascular resistances (36.3 +/- 2.5 and 3.2 +/- 0.3 mm Hg.min.m2/l, respectively) were increased. Significant increases occurred in total body water (36%), extracellular volume (81%), plasma volume (53%), and exchangeable sodium (63%). The renal plasma** flow was only moderately decreased (49%), and the glomerular filtration rate was normal. Significant **increases also occurred in plasma concentrations of norepinephrine (3.6 times normal), renin activity (7.2 time normal), aldosterone (3.4 times normal), cortisol (1.4 times normal), growth hormone (21.8 times normal),** and atrial natriuretic peptide (5 times normal)." "The arterial pressure is maintained more by the expansion of the blood volume than by an increase in the peripheral vascular resistance."

J Clin Endocrinol Metab 1991 Apr;72(4):768-72 **Expansion of extracellular volume and suppression of atrial natriuretic peptide after growth hormone administration in normal man.** Moller J, Jorgensen JO, Moller N, Hansen KW, Pedersen EB, Christiansen JS. Mech Ageing Dev 1983 Jul-Aug;22(3-4):233-51 **The anti-aging action of hypophysectomy in hypothalamic obese rats: effects on collagen aging, age-associated proteinuria development and renal histopathology. Everitt AV, Wyndham JR, Barnard DL Hypophysectomy in young male Wistar rats aged 70 days, like food restriction begun at the same age, retarded the life-long rate of collagen aging in tail tendon fibres and inhibited the development of age-associated proteinuria and renal histopathology. Hypothalamic lesions which increased the food intake of hypophysectomized rats from 7 g to 15 g/day and produced obesity did not alter the rate of either collagen aging or proteinuria development, nor reduce life expectancy, but increased the incidence of abnormal glomeruli. In the intact rats elevation of food intake from 7 g to 15 g/day increased the rate of proteinuria development, but did not affect the rate of collagen aging. Hypophysectomy was found to have a greater anti-collagen aging effect than food restriction, when food intakes were the same in both groups. These studies suggest a pituitary-hormonal effect on collagen aging and a food-pituitary-hormone-mediated effect on the development of age-associated proteinuria.**

Metabolism of glomerular basement membrane in normal, hypophysectomized, and growth-hormone-treated diabetic rats," Reddi AS, *Exp Mol Pathol,* 1985 Oct, 43:2, 196-208. "The in vivo synthesis of the renal **glomerular basement membrane (GBM)** collagen was studied in **normal, hypophysectomized (hypox), diabetic, and growth-hormone (GH)-treated diabetic rats....**" "A significant decrease in both proline and hydroxyproline specific activities were observed in GBM of hypox rats at all periods of study. Administration of GH to hypox rats returned the GBM collagen synthesis to normal. Diabetic GBM had higher proline and hydroxyproline specific activities when compared to normal rats. **Treatment of diabetic rats with GH for 10 days further increased both proline and hydroxyproline specific activities when compared either to diabetic or normal rats treated with GH.** The activity of glucosyltransferase, an enzyme involved in the biosynthesis of the disaccharide unit of GBM collagen was found to be decreased in glomeruli of hypox rats. In contrast, the activity of N-acetyl-beta-glucosaminidase, a glycoprotein-degrading enzyme, was found to be significantly increased in hypox rats. GH treatment restored both enzyme activities to normal. The results of the present study show that **GBM collagen synthesis is decreased in hypox rats and increased in diabetic rats. ....**not only normalized GBM collagen synthesis in hypox rats but also caused significant increase in diabetic rats. This suggests that the renal GBM metabolism is influenced by GH, and this may be of particular significance in view of GH involvement in diabetic microvascular complications."

THE ORIGINAL ARGUMENT:

Cancer is the result of ordinary physiological processes which become autonomous because of regulatory weaknesses in the organism.

Respiration is essential for the maintenance of the higher forms of life, and it is a respiratory defect, on both the cellular and the organismic levels, which allows cancer to persist and develop.

The heme group, because it serves many respiratory functions--hemoglobin, mitochondrial respiratory enzymes, steroid synthesizing enzymes, formation of thyroid hormone, detoxifying enzymes--is regulated in relatively primitive ways within each cell, and in more complex ways at higher organismic levels.

When the cell needs more respiratory energy, some fuel is diverted into the production of porphyrin, which is then turned into heme, which would normally provide for the efficient production of energy and protective factors.

When the efficient energy-producing systems are blocked, by injury, oxygen deficiency, toxins, or by the lack of one or more essential nutritional factors, heme production is activated.

Excess heme is destroyed by the enzyme heme oxygenase, which converts heme into biliverdin and carbon monoxide. Both of these factors have effects on the cell which are characteristic of cancer.

Estrogen, radiation, chemical carcinogens, and other forms of stress, activate the heme oxygenase enzyme.

Estrogen causes both porphyria and jaundice and is associated with increased formation of carbon monoxide. It inhibits many types of liver function, including detoxification.

The production of carbon monoxide by cancer cells can account for cancer's self-sustaining, "hereditary," property, without invoking genetic mutations which are now known to be consequences, rather than causes of cancer.

The production of carbon monoxide and biliverdin can account for many of the structural and biochemical abnormalities of cancer cells, and for their induction of abnormalities in adjacent cells.

"Genetic" theories of cancer have now reached a dead end, and the epigenetic, developmental-physiological approach remains as the only plausible description of cancer.

Carbon monoxide, estrogen, and the medical cancer cult

Previously when I wrote about the role of endogenously formed carbon monoxide in cancer, I probably didn't say enough about the way the idea fits into our cultural context. If an idea is very different from the existing cultural matrix, it's probably useful to consider it in its historical setting, and to contrast its theoretic models and implications with conventional models and practices, besides looking at some of the evidence that could confirm it.

During Otto Warburg's lifetime, many people working on the cancer problem were sufficiently aware of his work (because of his Nobel prize) that they occasionally mentioned it dismissively. Now, very few people even know about his cancer research and his conclusion that the prime cause of cancer is a cellular respiratory defect. For about 30 years, the dunces were in confederacy against him, then they forgot what it was about his work that had bothered them.

Dean Burk, who was head of the cell biochemistry laboratory at the NIH for many years, was the only well known American who defended Warburg's interpretation of cancer, and now that they both have died, cancer researchers just don't feel the need to mention Warburg's work at all.

In practice, science isn't a matter of a rational evaluation of evidence, but rather it's a matter of power, funding, and propaganda. In our culture, the understanding of cancer has been guided since the late 1940s by the propaganda of the American Cancer Society, supported by the corporate cancer industry and, especially since Nixon's War on Cancer began in 1971, by government funding.

Warburg's work showed that anything which causes tissue atrophy contributes to the development of cancer, and that interference with the

cells' ability to use oxygen for energy production was the essential factor in cancer. Warburg was exploring this simple deterministic biochemical, physiological and developmental process in Germany just as quantum mechanics was destroying classical physics and Nazism was enforcing the dogma of genetic determinism and eugenics. The revision of Darwinism taking place at this time turned the doctrines of random mutation of genes and selection of "superior genes" into the essential core of biology and medicine.

The same concepts were used to describe socially undesirable people (people whose genes had "degenerated") and the biologically undesirable cells of cancer.

There were reasons for commerce and government to favor a theory of cancer in which a mysteriously random process turned a normal cell into a deadly alien cell that multiplied wildly and invaded and destroyed surrounding healthy tissues. One reason was that causes of cancer, such as soot, radiation, and estrogen, would become very unpopular if the public recognized the causal pathways between them and cancer, and polluters could be sued or accused of murder, and drug companies would lose the chance to market all of their infinitely profitable estrogens.

And the idea of a mysteriously mutated cancer cell ruled out the idea of any therapy that would cause the cancer to regress or disappear in a physiological manner that didn't harm any other part of the body. The already established treatments of surgical removal, destruction by radiation, or destruction by cytotoxic chemicals were justified by the doctrine that the tumor, the clone of cells produced from the mutant cell, was irreversibly committed to its condition.

The scientific foundation for that view of cancer has really been destroyed over the last fifty years, but it is rare to encounter a physician or professor of medicine who is aware of that. Even the majority of biology professors haven't realized the decisive nature of the evidence against it, because most of them don't read outside their own specialty.

Oncology (which should mean the study of tumors) is really a medical religion, filled with rituals and incantation-like use of language. Despite the abundant evidence that access to medical diagnosis and treatment doesn't improve health, most people are mysteriously bound to the "health care system." Hotels don't have 13th floors, many people don't like it when a black cat crosses their path, or they knock on wood at odd moments in a conversation, even though they aren't superstitious. The culture influences behavior, just by being there. When your friends recite their version of the medical incantations, and your doctor repeats them while wearing a white jacket and expensive shoes, it seems only decent to go along with the system. Even if patients would like to question their doctors' assumptions, they can't do it successfully within the medical culture, and few people are willing to take a hostile stance toward a system that monopolizes many useful drugs.

The mutant cell/clonal theory of cancer reduces the issue to a matter of choosing the best way to kill the patient's tumor without killing the patient. Very slowly, the practice of using a single modality against each type of tumor is being replaced by trials using several substances at the same time, or sequentially, and oncologists now sometimes magnanimously allow their patients to take vitamins as well as psychotherapy, though many have feared that the vitamins might interfere with their work.

Outside the medical world of oncogenes and mutations, the understanding of cancer as a disorganization of metabolism and regulatory processes is advancing.

Johanes Muller argued in 1840 that cancer might originate at the level of tissues, rather than in the nature of the individual cells making up the tissue. More recently, David Smithers described cancer as a problem of organization, analogous to a traffic jam, which can disrupt the system even while no particular vehicle is defective. Generally, this view speaks of a "cancer field," in which whole regions of an organ show different degrees of a precancerous or cancerous state.

The "precancerous" condition of some of the cells within the cancer field can be shown to be induced by something emitted by seriously injured cells nearby. In radiation research, these effects are now described as the "bystander effect," in which unirradiated cells that are exposed to

radiation-damaged cells will develop some of the physiological features of the irradiated cells. Some kind of "toxic signal" has been released from an injured cell, inducing a similar injury in the healthy cells.

Irradiated tissues respond with most of the features that are involved in general systemic stress--lipid peroxidation, free radicals, increased glycolysis, and a shift of metabolism toward production of the "emergency" factors that increase resistance in the short term. Other kinds of injury--overstimulation or energy deprivation, for example--cause cells to produce the same sorts of signals that affect surrounding cells. The extracellular matrix in which cells are embedded transmits these signals, partly by undergoing its own transformation into a differently structured matrix.

Systemic metabolic problems make local problems worse, and if a local injury is serious, it can cause the liver to produce stress-related proteins called "acute phase proteins," including fibrinogen and serum amyloids A and P, C-reactive protein, and other inflammation-related proteins. These proteins are a primitive sort of immune system, that can directly bind to some harmful substances. Endotoxin absorbed from bowel bacteria is probably the commonest reason for increased production of these proteins. The acute phase proteins contribute to the development of tumors in various ways. For example fibrinogen degradation products are pro-inflammatory. Although these are called acute phase proteins, they sometimes might better be called chronic inflammation proteins, since they are associated with diabetes, cancer, and heart disease.

The systemic principle of cancer involves the same inflammatory mechanisms that are involved in circulatory diseases, strokes, multiple sclerosis, multiple organ failure, etc. An inflammatory process that isn't controlled causes blood vessels to leak, and the process of disposing of the leaked materials, if the leakage is extensive, leads to reactions of the whole organism; usually, the signals reaching the higher levels of organization evoke a stress-limiting response, and stability is restored, but if conditions aren't just right, the stress-induced damage accumulates. With repeated injury, and with chronic accumulation of polyunsaturated fats, fibrosis, atrophy and inflammation increase, and the energetic intensity of corrective responses decreases.

The first reaction to serious injury, challenge or deprivation is to prepare for growth and cell division. The simple production of lactic acid when oxygen supply isn't adequate causes blood vessels to dilate. Energy production becomes inefficient; the fatty acid synthesizing enzyme system is activated, even when large amounts of fat are being made available by lipolysis under the influence of stress. In proportion to the challenge, capillaries become more permeable, and cells may begin to enter the tissues from the bloodstream, along with water and nutrients. A surge of cell division allows renewal of damaged cells. If the inflammation persists, new capillaries grow, and larger vessels develop. Some of the immigrant cells may eat themselves to death removing debris, but others remain as colonists. Every inflammation is an incipient neoplasm. An organ such as the intestine, the liver, ovary, or thymus gland, is always in flux, renewing its cells, but when that renewal is disordered, the functions of the organ change, such that we speak of a neoplasm, a new growth, which in a sense is a new organ. It has been suggested (Zajicek) that the neoplastic organ has an adaptive, survival value, producing one or more substances that the body lacks.

Zajicek supports his idea with careful analysis of cancer statistics, and points out that it's very common for the removal of a large tumor to be followed quickly by the appearance of myriad small tumors. He thinks it would be better to leave the original tumor in place. His orientation is in the tradition of "chalone" research, in which every tissue stops growing at the proper time because it emits a substance which specifically inhibits its own growth. Over the last 50 years the idea has been confirmed by many experiments, but it hasn't made any impression on the cancer industry. Stating the idea in very broad terms, we might say that aging or stress causes atrophic processes including "sarcopenia" and "osteopenia," the reduction of the mass of various tissues below the proper level, and that tumors are the result of an uneven attempt to restore the proper mass of tissue.

I think Zajicek's idea would be more acceptable if it were stated in more general terms, without denying the possible role of chalones, or something like chalones that tends to protect the body or suppress tumors. Using Le Chatelier's principle,* that a system adjusts to disturbance in a way that reduces the disturbance, we could say that one function of a tumor might be to dispose of something that has disturbed homeostasis.

For example, insulin resistance produces an inability to oxidize glucose, and is associated with chronic hyperglycemia, or "type 2 diabetes." Diabetes of that type is associated with a high risk of cancer (e.g., Yam, et al., 1996). V.S. Shapot's decades of research led him to describe a tumor as a glucose scavenger (1979). When the system is disturbed by chronic hyperglycemia and an inability to use glucose, a sort of equilibrium will be restored by the production of a tumor that pumps glucose out of the system. Although tumors consume sugar and release lactic acid, they aren't really living on the sugar, they are doing something very odd: They convert a large amount of glucose into fat, and then oxidize the fat. The enzyme system, fatty acid synthase (FAS), is an effective way to dispose of glucose, because of its energetic inefficiency.

Another way to look at Zajicek's idea is to recognize that the main cause of insulin resistance is the dietary consumption of (both omega -6 and omega -3) polyunsaturated fatty acid, and that the fats produced by the FAS in tumor cells are mainly saturated fatty acids, with some of the antiinflammatory omega -9 series. In this case, Zajicek's suggestion that the tumor is producing something the body needs would be literally correct.

The same "epigenetic" processes that create our organs, under new conditions can create tumors. The doctrine of genetic determinism has almost reversed the basic meaning of "epigenetic," since developmental biologists talk as if developing organs were all programmed in the genome, and that they were created as if from a blueprint contained in the genes. During ordinary development, we think of epigenesis as a process that creates an organism in a certain environment, and we recognize that even the protected intrauterine environment allows great individuality of development, influenced by slight differences in conditions of nutrition, hormones, temperature, etc., during an individual's development. Epigenesis accounts for a lot of normal variation in traits--size of brain and other organs, rate of maturation, degree of pigmentation, etc.--and for many developmental defects. Epigenesis is an even more important concept for understanding tumors, despite the fact that so much money has been invested in explaining tumors according to oncogenes and other ideological inventions of the genetic determinists. Even oncogenes' expression is environmentally determined.

The normal cyclic function of the ovaries is a model for the potentially creative role of an inflammation-like stress. Every month (in a rhythm influenced by many cues), a productive crisis comes to a focus in the ovary, with the formation of estrogen, prostaglandins, carbon monoxide, and other signal substances, causing rapid changes both locally and systemically, with water, hormones, and nutrients gathering around the ovum (as well as in other parts of the body, such as the feet). Then as the follicle ruptures with the release of an ovum, the excitatory, inflammation-like state is resolved, with a massive increase in the production of the antiinflammatory, antistress substance, progesterone, leading to the suppression of the excitatory substances. **These monthly processes are developmental, they are part of the epigenetic development of the organ.**

Most, if not all, of the substances involved in ovarian physiology are involved in the diseases of stress and degeneration, which progress in proportion to the inability to produce the resolution of inflammation and restoration of the stable condition. The ovary is a major source of estrogen, which can produce the excited, activated, inflammatory and proliferative state in any tissue of the body, though it acts mainly on the uterus, breasts, and pituitary. But the ovary is also, in response, able to produce massive amounts of the protective progesterone, which interrupts the inflammatory effects of estrogen on the various tissues and organs, largely by suppressing the proteins that hold estrogen within cells (especially the "estrogen receptor"), but also by changing the activities of many enzymes away from the

estrogen-controlled, inefficient pattern. **The developmental actions of the ovary cause continuing epigenetic processes in other organs, causing noticeable changes in their structure every month.**

The ovary plays a specialized coordinating role in preparing the whole body for pregnancy, but most of its regulatory features can be seen in a diminished form in other organs, and in any tissue that is unable to completely resolve a crisis of inflammation. Considering ovarian processes and structures in detail will offer some insights into the processes that occur elsewhere during inflammation and tumefaction.

One of the rules of classical mechanistic endocrinology was that a hormone doesn't act on the organ that produces it, and acts only on its "target organ," one with the special "receptors" that allow it to recognize and respond to the hormone. But now, all organs are known to contain "estrogen receptors," and many of those same organs can produce very significant amounts of estrogen. The ovary, according to the classical doctrine, wouldn't be able to respond to estrogen. Oral contraceptive manufacturers used that idea to argue that excessive estrogen couldn't cause ovarian cancer, and in fact prevented it, by preventing ovulation. But the cells of the ovary do respond to estrogen, multiplying, and during *in vitro* exposure, developing a pre-cancerous appearance. For more than 20 years, there has been clear evidence that use of supplemental estrogen increases the incidence of ovarian cancer.

Related claims were made about estrogen and the prostate gland for more than 50 years: "Estrogen can't do anything to a male organ except to decrease its maleness," that is, it couldn't stimulate cell division or cause prostate cancer, but it would cause the prostate to shrink, and prevent prostate cancer. Many of those claims are still being made, and estrogen is still being prescribed to treat it by a large portion of the medical profession, though experiments are demonstrating estrogen's clear contribution to the prostate gland's degeneration into cancer.

The ovary has been a focus of several types of ideology in biology, and as a result real investigation of ovarian physiology has been retarded for 100 years. Weismann's genetic doctrine of the "isolation of the germ line" led to a false theory of ovarian aging, the egg-depletion theory. Despite the absence of evidence for the finite-egg-supply theory, and the increasing accumulation of evidence that eggs are continually produced in adult ovaries, many people still cling to the unfounded theory. The real nature of ovarian aging is very similar to the aging of any organ, and the extreme specialization of the ovary makes some of the issues clearer when we look at analogous processes in other organs, such as the prostate, or breast, or uterus, or the "adventitious organs" of inflammation and tumefaction.

In the normal ovary, under the influence of the pituitary follicle stimulating hormone, several pockets of fluid (primary follicles) begin forming in the ovary, and the largest of these follicles suppresses the development of the others, so that only one usually reaches full development. Under the influence of the pituitary luteinizing hormone, progesterone, and other substances, the ovum completes its meiosis, the follicle ruptures and the ovum along with the fluid containing a high concentration of estrogen is released. The cells that had surrounded and supported the ovum (granulosa cells) multiply to fill the space, forming the corpus luteum, the yellow body that produces mainly progesterone. The corpeus luteum is a thoroughly new organ that's produced periodically, under the influence of chains of interacting stimuli.

Warburg's main point about cancer was that it always has a "respiratory defect," causing it to produce lactic acid even in the presence of oxygen (a process called aerobic glycolysis), while oxygen causes normal cells to suppress lactic acid formation (this is called the Pasteur effect). Warburg believed that this defect in the cells' energy production system meant that it lacked the ability to perform many of its normal functions, but that it remained able to divide. He also believed that oxygen deprivation was one of many stressors that could damage the cells' respiratory system, and he showed that even very small tumors are usually very hypoxic. Other experimenters (including Hans Selye) found that mechanical barriers such as a glass tube or a bent piece of plastic film implanted into an animals

tissues would cause cancer to develop among the enclosed cells (following a period of atrophy).

There are a few normal situations in which aerobic glycolysis occurs--the retina, the ovarian follicle during its preparation for ovulation, the Sertoli cells of the testicle, which are involved in the maturation of sperm cells, and sometimes in the placenta. Except for the retina, these tissues are subject to strong stimulation by estrogen, which stimulates lactic acid formation while interfering with oxygen use. Aerobic glycolysis is associated with the formation of fatty acids (R.A. Walli, 1978), by the enzyme fatty acid synthase, which is increased by estrogen, and the activity of which corresponds to the malignancy of many types of cancer.

Estrogen and other stimuli can cause the formation of lactic acid even in the presence of oxygen (i.e., aerobic glycolysis). Lactic acid has some hormone-like actions, causing, for example, vasodilation and increased permeability of capillaries. It has been suggested that it has some involvement in the process of meiosis, in the formation of mature germ cells.

There are some compartments in the body that have very little oxygen, and that are damaged by increased oxygen. The thymus maintains a very low oxygen tension, but it has a strong Pasteur effect, so normally doesn't produce excess lactic acid. The testicle stops producing testosterone if the oxygen is increased too much. The vitreous body of the eye normally has low oxygen tension.

A special feature of the ovary is that the cells around the ovum are not only isolated from the blood supply, causing localized hypoxia, but they are also (unlike the hypoxic thymus) stimulated by estrogen.

In the expanded ovarian follicle, the ovum is a considerable distance from the closest blood vessels, and so it and its adjoining cells receive very little oxygen. Glucose diffuses into the follicle, and the granulosa cells around the ovum metabolize it into lactic acid. The concentration of lactate in the follicular fluid increases, along with estrogen, as the follicle matures, approaching ovulation. Immediately following ovulation, the granulosa cells multiply, filling the space that was formerly the follicle, and the blood vessels that had surrounded the follicle now infiltrate the developing corpus luteum, so that it receives an abundant oxygen supply as it begins forming progesterone.

The permutations of these variations in oxygen tension, glucose supply, and excitatory stimulation can account for a variety of developmental processes, and the resulting concentrations of lactic acid, carbon dioxide, fatty acids, and pH increase the range of formative possibilities. Carbon monoxide has the ability to mimic hypoxia even in the presence of oxygen.

Estrogen, in many different organs, increases the production of the enzyme heme oxygenase, which produces carbon monoxide, which inhibits respiration and also inhibits a variety of enzymes that use the heme group. (Tian, et al., 2003, 2004; Tschugguel, et al., 2001).

In the ovary, carbon monoxide increases the production of estrogen, but decreases the production of progesterone. An excess of estrogen, acting partly through the increased carbon monoxide, blocks the formation of progesterone, and prevents a successful ovulation.

These are just some of the interactions within the ovary that are similar to processes in the cancerization process wherever it occurs. Any inflamed tissue becomes subject to estrogenic stimulation, by the activation of enzymes, especially beta-glucuronidase, which cause estrogen to be deposited in the cells. Any hypoxic tissue, including inflammations of any sort, will express the heme oxygenase enzyme, producing carbon monoxide. Presumably, in the short term, these increases of estrogen and carbon monoxide have their adaptive functions, such as stimulating cell division for healing, and blocking some kinds of free radicals and excessive calcium uptake. But, as in the ovary, when the system isn't able to suppress them, they become self-sustaining, and begin to spread their influence to neighboring cells. Cancer cells are very resistant to injury from free radicals, which in normal cells accelerate the spontaneous dissolution called apoptosis, and carbon monoxide is one of their defense mechanisms, that makes them relatively immortal (Ghattas, et al., 2002).

When an organism is functioning normally and adapting to stresses, the operation of a functional system, including the part of the

nervous system that coordinates the function, causes that system to be stabilized, and to become more efficient, and even to grow. Work causes muscles and bones to enlarge and become stronger, learning causes the brain to grow. Chronic inflammations have some of the properties of a functional system, with participation of the nervous system, adjustments of the immune system, and changes in the circulatory system, except that the normal and desirable functions are progressively lost, rather than improved. The operation of the short term protective measures contribute, if they persist too long, to atrophy and fibrosis, and potentially, to disordered growth.

In some cases, we know that an excess of stimulation, in reaction to the organ's reduced functioning, promotes the growth and spread of a tumor, for example, prolactin contributes to breast cancer, thyrotropic hormone to thyroid cancer, and gonadotropin to ovarian cancer. Ovarian teratomas are now believed to be parthenogenic, deriving from an unfertilized ovum, and I have suspected that the direction of their development reflects the endocrine situation, for example when a teratoma consisting of thyroid tissue appears in a woman who has taken extremely big doses of iodine for a long time.

In the chronic inflammatory state that develops with stress and aging, besides the extrinsic stimuli that were the subject matter of classical endocrinology--pituitary hormones driving the ovaries, ovarian hormones driving the uterus, etc.--the inflamed tissues begin to stimulate themselves: The breast and uterus begin to synthesize estrogen, for example.

Some of the things produced by tumors, such as estrogen and carbon monoxide, appear to be the result of a short-term adaptive factor that becomes maladaptive when the system can't turn it off. It's generally assumed that when a tumor produces a hormone, its effects will necessarily be harmful, but sometimes it isn't clear whether they are harmful or beneficial, and in a few cases, they clearly seem to be beneficial.

Many cancers cause a great increase in the concentration of calcium in the blood, and this is often the result of the production of parathyroid hormone-related protein (PTH-rP) by the tumor. In some cases, PTH-rP can induce apoptosis by causing cells to take up calcium, but in other cases it is a survival factor, for example for nerve cells in the brain. Some experiments show that increased calcium in a tissue suppresses heme oxygenase and carbon monoxide (Zhang, et al., 2003, 2004). PTH-rP and the parathyroid hormone itself have some functions that overlap with those of vitamin D, which is now known to help to suppress many cancers.

Inhibitors of fatty acid synthase cause many types of cancer cells to die. Vitamin D, which stops the growth of breast, prostate, and bowel cancer cells, inhibits FAS (Qiao, et al., 2003). This could be another example of Zajicek's principle, since it has been discovered that prostate and other **cancer cells are able to create the active form of vitamin D.** Vitamin D also acts as an antiestrogen, and estrogen is a factor in the development prostate cancer, breast cancer, and many other types of cancer (Swami, et al., 2000; Demirpence, et al., 2001).

In some cancers, vitamin D operates through ceramide (Pirianov and Colston, 2001), Palmitic acid, is a product of FAS and a component of ceramide, which inhibits cancer cell growth.

Understanding the causes of tissue atrophy as a failure of energy that allows inflammation to become chronic, leading to a disorganized attempt to regenerate tissue and stabilize the system, our response to both atrophy and cancer should be to restore metabolic processes of the highest type, based on the oxidation of glucose with the production of carbon dioxide, rather than lactic acid and fatty acids, and to eliminate inflammation and its products that have disrupted the normal balance between cell renewal and cell elimination. Aspirin, by inhibiting the production of estrogen, of carbon monoxide, and of several cytokines and toxic lipid products, and by supporting normal respiration, helping to correct hyperglycemia, and suppressing lactate production, is an especially valuable therapy. Sacca et al., have recently (October, 2004) demonstrated that aspirin's anticancer effect appears to involve the inhibition of heme oxygenase.

Caffeine, by inhibiting FAS and sparing glucose, and inhibiting many of the toxic lipid

products and other inflammatory mediators, should have at least additive effects when combined with aspirin.

Vitamin D, by its antiestrogenic and antiinflammatory actions, and by suppressing FAS, parallels the effects of aspirin and caffeine in several ways.

Gelatin, by lowering serotonin, should help to prevent excessive activation of heme oxygenase and formation of carbon monoxide during injury or stress (on the role of serotonin: Sharma and Westman, 2003; Sharma, et al., 2003).

The lower incidence of, and mortality from, cancer at high altitudes might partly be explained by experiments that show that reduced atmospheric oxygen tension down-regulates heme oxygenase in human cells (Kitamuro, 2003).

THE ARGUMENT:

Cancer is the result of ordinary physiological processes which become autonomous because of regulatory weaknesses in the organism.

Respiration is essential for the maintenance of the higher forms of life, and it is a respiratory defect, on both the cellular and the organismic levels, which allows cancer to persist and develop.

The heme group, because it serves many respiratory functions--hemoglobin, mitochondrial respiratory enzymes, steroid synthesizing enzymes, formation of thyroid hormone, detoxifying enzymes--is regulated in relatively primitive ways within each cell, and in more complex ways at higher organismic levels.

When the cell needs more respiratory energy, some fuel is diverted into the production of porphyrin, which is then turned into heme, which would normally provide for the efficient production of energy and protective factors.

When the efficient energy-producing systems are blocked, by injury, oxygen deficiency, toxins, or by the lack of one or more essential nutritional factors, heme production is activated.

Excess heme is destroyed by the enzyme heme oxygenase, which converts heme into biliverdin and carbon monoxide. Both of these factors have effects on the cell which are characteristic of cancer.

Estrogen, radiation, chemical carcinogens, and other forms of stress, activate the heme oxygenase enzyme.

Estrogen causes both porphyria and jaundice and is associated with increased formation of carbon monoxide. It inhibits many types of liver function, including detoxification.

The production of carbon monoxide by cancer cells can account for cancer's self-sustaining, "hereditary," property, without invoking genetic mutations which are now known to be consequences, rather than causes of cancer.

The production of carbon monoxide and biliverdin can account for many of the structural and biochemical abnormalities of cancer cells, and for their induction of abnormalities in adjacent cells.

"Genetic" theories of cancer have now reached a dead end, and the epigenetic, developmental-physiological approach remains as the only plausible description of cancer.

Carbon Monoxide, Stress, and Cancer: 1999 status

When we thoroughly understand cancer, we will be closer to understanding life itself.

Cancer, AIDS, and extreme hypothyroidism have several features in common--they cause tissue loss and organ damage, with immunodeficiency and intense activation of the stress hormones, including cortisol. In cancer and AIDS, a good case has been made for the primacy of stress-induced wasting as the main cause of death. Whatever one might believe to be the cause of cancer and AIDS, it is always good for the patient to prevent tissue damage from the stress associated with the sickness. Since the stress hormones primarily destroy tissues by the activation of specific proteases, the use of protease inhibitors for treating AIDS is probably helping to prevent tissue loss, as an unintended side effect. But in the case of cancer, there are good reasons for believing that metabolic dysregulations are the cause of the disease itself, as well as of the wasting symptoms.

When I wrote about carbon monoxide as a cancer hormone a few years ago, some people were confused, and I think that was because I didn't explain in detail how Otto Warburg's work made the idea seem so obvious.

In studying the pigments of cellular respiration (enzyme cofactors, including vitamin B2 and the cytochromes), Otto Warburg (1926) found that carbon monoxide, the respiratory poison, bound to some of the crucial pigments, and that light would free the pigment from the carbon monoxide, restoring respiration. Despite the fact that his work is described in all biochemistry textbooks, until very recently the toxicity of carbon monoxide was ascribed by medical texts only to its

effects on hemoglobin, preventing the delivery of oxygen to cells, rather than to its effects on the respiratory pigments in the mitochondria, as demonstrated by Warburg. Of the thousands of publications on the toxicity of carbon monoxide in recent decades, its effects on mitochondrial metabolism have hardly been investigated, because of the persepective that it was a poison coming from outside the body, and that its effect on hemoglobin was sufficient to cause death, so the question of its effect on the mitochondrion was medically irrelevant.

In his famous theory of cancer, Warburg argued that cancer was always characterized by "a respiratory defect," and he argued that many things could damage the respiratory system and lead to cancer. He and his colleagues over several decades showed that all the known causes of cancer produced the characteristic respiratory defect of cancer, in which cells would produce lactic acid even in the presence of normal levels of oxygen. This is called *aerobic glycolysis*, and in normal cells, the production of lactic acid is *anaerobic*, since the availability of oxygen suppresses the production of lactic acid, and causes carbon dioxide to be produced instead. (This effect of oxygen is called the Pasteur effect, and I think it is largely the production of carbon dioxide which accounts for it, though other things such as the level of ATP contribute to it.)

Warburg showed that chemical carcinogens, radiation, prolonged culture without adequate oxygen, and even vitamin B1 or B2 deficiency would promote first the characteristic cancer metabolism, and then actual cancerization. Most cells with the respiratory defect simply died, and it was those which could adapt to live with the defect which became cancerous. The tumor which results from a metabolic defect will "epigenetically," secondarily, develop chromosome imbalances, which may approximately coincide with the cells' transformation into cancer, and the conditions within the tumor will increase the tendency to produce mutations, which are not likely to be repaired in the extremely stressed state of the cells.

I think the reason Warburg didn't explore the role of carbon monoxide in cancer was simply that, during his lifetime, it wasn't recognized as something which is produced in the body. **Warburg had no reason to suspect that carbon monoxide would be produced by the cell exactly when the cell's respiratory apparatus was challenged. But since about 1971, carbon monoxide has been recognized as a normal product of the degradation of heme, approximately at the same time that it has become clear that respiratory distress on the cellular level stimulates both the synthesis and the degradation of heme.**

Unfortunately, after Warburg's death, there were no prestigious advocates of his theory, and his death coincided with America's "war on cancer," which consisted of giving huge public funding to the "cancer genetics" estrablishment, people who were congenitally hostile to the concept that cancer had knowable or controllable causes. Industry and medicine found it convenient to argue that people were responsible for their own diseases, in the sense that they inherited them, as a kind of mechanistic karma. *Mutations in the inherited genes were, by definition, "random," which gave them the virtue of being impossible to pin down to a specific, legally actionable, cause.*

The genetic, and thus "essential," nature of cancer justified the concept of treating it by killing it. (The procedure William Blake described 200 years ago as "curing the pox by cutting out the spots.") The doctrine of genetic causality indicated that only capital punishment could deal with the traitor-genes. Although these essentialists at first had rejected the idea that viruses could integrate themselves within our genes, after several years they realized that this idea meant that the infectious disease establishment could join forces with the genetics establishment. The new, highly funded "oncogene" establishment had absolute control over cancer research, and that direct control spread indirectly, like a malignancy, throughout academic and commercial biology.

Most people in the contemporary medical industry are so fond of the idea of DNA-mutation, followed by "clonal selection," to explain cancer, that they are able to ignore the many types of

evidence that show cancer to be a process of deterioration in a mass of cells, rather than a progression of a single cell through stages of DNA mutation.

This obsessive belief that "DNA causes everything" goes back to Weismannism, and the Neo-Darwinism that he founded by presenting his--purely arbitrary--arguments to eliminate the inheritance of acquired traits from the theory of evolution, and--*opposing Darwin*--to claim that Natural Selection was the only force in evolution. Weismannism, in its absolute rejection of the environmental adaptationism of Darwin and Lamarck, was almost a reversion to Preformationsim. In its insistence on the "isolation of the germline," or the *immortality of the germline* which was passed on in the germ cells of the gonads, Weismannism subscribed to the Preformationist belief that all future generations are contained in the germ cell, and its adherents tried to justify this by asserting that the *soma,* all the rest of the individual outside of the germ cells, was nothing more than a mortal shadow of the essential (genetic) immortal being, since the body was produced precisely by the **deletion** of the information contained in the germ cell. (This doctrine was behind the denial that animals could be cloned from the nucleus of body cells. Even after frogs, sheep, and cows were produced in this way, there were some people who couldn't accept the results as facts. The doctrine that "telomeric shortening" causes aging came straight out of Weismannism.)

Of course those ideas were false, nothing but an absurd application of Rationalist philosophy to biology to eliminate Darwin's "materialism," but the doctrine's importance is undeniable, since its direct influence can be seen in every university biology course and textbook of the 20th century.

It is this essentialist commitment of the cancer establishment that has made Warburg's work practically disappear from the academic culture. His demonstration that the cancer metabolism could be reversed by vitamins was a threat to the entire foundation of twentieth century essentialist medicine.

Poor Nutrition + Estro
= ↑ porphyrin

Because of my interest in the effects of light on the hormones and respiratory energy production, and my long-standing interest in Warburg's view of oxygen's role in evolution and cancer, and my awareness that *porphyrins** were at one time thought to be cancer hormones, it seemed obvious to think of carbon monoxide as a cancer hormone.

I happened to become acquainted with Leonell Strong, who developed the strains of cancer-prone mice that have been used in breast cancer research. ***Although he was a geneticist and bred the mice that demonstrated the inheritance of cancer, he also showed that simple therapeutic measures would not only prevent cancer in a susceptible individual, but would also prevent cancer in many generations of the treated animal's descendants.*** Strong discovered that estrogen and poor nutrition lead to overproduction of the porphyrin pigment, and contribute to the development of cancer. He showed that the liver was involved in the control of cancer. The Shutes, the Biskinds, and Alexander Lipshutz were at this time revealing other effects of estrogen that illuminated Strong's discoveries.

Besides Strong, who showed individual and hereditary avoidance of cancer, many other workers have demonstrated that "established" cancer cell lines can be induced to revert to normal tissue. Inheritance isn't indelibly fixed. A *physiological state* is passed on. Since carbon monoxide produces a respiratory defect, and is produced during respiratory deficiency, it is one of the factors which can account for the "heritability" of cancer. When cancer cells are implanted into a healthy host, they seldom gorw, but when implanted into a host who already has cancer, they grow. (Hakim, 1988.) The healthy host provides many restorative factors, the sick host provides additional harmful factors, but few restorative factors (Chekulaev, et al., 1987.)

*(*Porphyrins are the pigment molecules that include the heme of hemoglobin, of the respiratory cytochromes, the peroxidases including thyroid peroxidase, and of the P-450 enzymes which, among other things, produce steroid hormones.)*

One of the mysteries of public health is that people who drink alcohol live longer and are generally healthier than people who don't. 30 years ago, when I began studying Warburg's work, I heard about a man with inoperable cancer who, because of his hopeless condition, began living almost exclusively on hard liquor. Aftrer six months his doctor wondered why he was still alive, and a new operation revealed that there was no cancer.

In Warburg's view, cancer has a unique requirement for glucose, because of its "respiratory defect." The ability of cancer to consume large amounts of glucose means that the body interprets cancer as stress, since the waste of glucose is the key feature of stress. The body's response to decreasing glucose is to produce larger amounts of adrenal hormones, especially cortisol. Cortisol raises the blood glucose supply by converting tissue proteins into sugar. This hormonal response to the sugar appetite of cancer is the main cause of the wasting syndrome which makes cancer so serious, and which destroys the thymus gland, causing the immune system to lose its guidance. V. S. Shapot's work, showing the involvment of glucose and cortisol in cancer, provides part of the context for understanding the implications of Warburg's view of cancer as a "respiratory defect."

Alcohol has the ability to lower blood glucose, but it does it partly by suppressing the stress-induced secretion of cortisol, reducing the conversion of the body's proteins into glucose, and shifting metabolism toward fat as an energy source. Additionally, ethyl alcohol happens to detoxify carbon monoxide, "desorbing" it from the heme groups, somewhat as light does. These properties of alcohol have been studied in hospitalized patients. In terminal cancer patients, it was found to be extremely effective in protecting against the tissue wasting process. Even in alcoholics with liver cirrhosis, it was found to be protective to the liver, when added to a good diet.

Ordinary stress lowers blood sugar and produces lactic acid, because it uses energy faster than cells can produce it by way of efficient oxidative metabolism, and so sugar is inefficiently converted to lactic acid. This form of metabolism raises the cell's internal pH, intensifies its negative electrical charge, and causes it to take up water, and to alter its control of salts and other solutes; these changes may stimulate cell division, but they can also cause cell death, or adaptive modifications.

While the genetic, the metabolic, and the adaptive processes seem to be on very different "levels," if we are to think about them in realistic and productive ways, it's necessary to follow the ways in which they are integrated, and to see *gene regulation and metabolic responses to the environment as a continuous physical-chemical process.* The myth of the isolated immortal germline, and its derivative, the "Central Dogma" of molecular genetics, that sees information flowing only from the genes into the proteins, have kept most researchers from looking elsewhere for regulatory principles.

The idea of inheritance as a rigidly fixed system has made it easy to think of biology in terms of the "lock and key" analogy, in which an enzyme and its substrate, an antibody and its antigen, an organism and its niche, a gene and its inducer, etc., have a specific, fixed, mechanical relationship. However, even the simplest organisms have qualities that can seem more like a locksmith who with a little time can figure out how to open locks without a key. All biological systems are simultaneously regulated on more than one level, in a coherent and unified way.

The cell's framework, the "cytoskeleton," was demonstrated early in the 20th century, but the dogmatic view of the cell as "liquid enclosed by a membrane" caused it to be ignored by most biologists until the 1970s. The cytoskeleton is strongly influenced by respiratory distress and the hormones that are so closely associated with oxidative processes, estrogen and the porphyrin derivatives in particular.

The cytoskeleton includes a variety of filaments and tubelike structures. The microtubules make up the apparatus that separates the chromosomes during cell division. Estrogen can cause almost instantaneous changes in the cytoskeleton proteins and their interations with

have a variety of actions that tend to improve respiration.

Things that protect the bowel, such as raw carrots, have far-reaching effects on hormones and immunity. Eggs contain many protective and therapeutic factors, in spite of their excess of toxic unsaturated fats resulting from an unnatural diet; egg lecithin, for example, isn't immunosuppressive, as soybean lecithin is.

The last experiments of Leonell Strong, in which he found that certain combinations of nucleosides could cause the disappearance of cancer from the progeny of the treated animals, should be taken seriously. They relate to the heritable effects of hormone balance ("hormonal imprinting"), and so have implications far beyond the prevention of cancer.

These are aimed at killing the intruding cells. However, in cancer patients the tumor continues to grow.** As tumor cells proliferate, they were shown to release factors that mediate the inactivation of the host immune defense systems. The study documented in this article examined peripheral blood lymphocytes, mononuclear cells (MNC), NK cells, T-helper cells (THC). This study confirmed the interaction of the released inhibitor factors with these mononuclear cells." "An elevation in the expression of cell surface antigen GP-120 has been observed to be associated with the activation in vitro of T-cells from healthy adults and from patients with benign breast disease, but not of T-cells from patients with breast carcinoma."

Endocrinology 1996 Nov;137(11):4536-41 **The cellular protooncogenes c-fos and egr-1 are regulated by prostacyclin in rodent osteoblasts and fibroblasts.** Glantschnig H, Varga F, Klaushofer K PGs are local regulators of various cellular functions. They exert their effects via specific PG receptor subtypes. **Induction of c-fos gene expression has been described for arachidonic acid and its metabolite PGE2.** We demonstrate that another very short half-lifed prostanoid metabolite, namely prostacyclin (PGI2), is a regulator of immediate-early genes. PGI2 transiently induced the growth-associated immediate-early genes c-fos and egr-1 in osteoblastic as well as fibroblastic cell lines. Furthermore, we showed that **PGI2 dose dependently stimulated new DNA synthesis in the osteoblastic cell line MC3T3-E1.** Although PGI2 is known to be a potent inducer of cyclooxygenases, we showed that this **pathway is not necessary for protooncogene induction by PGI2. Our data indicate a direct effect of PGI2 on immediate-early gene** expression, which does not depend on the synthesis of other prostanoids. Intracellular signal transduction mechanisms were studied with the protein kinase inhibitor H-7, a potent inhibitor of PGI2-induced c-fos expression. Experiments with phorbol esters revealed that protein kinase C activity is not obligatory for the effect of PGI2 on c-fos expression. We conclude from these results that PGI2, a rapidly inactivated prostanoid, has a major impact on cellular oncogene expression and growth in mesenchymally derived cells.

Proc Natl Acad Sci U S A 1998 Nov 10;95(23):13692-7 **Genetic instability of cancer cells is proportional to their degree of aneuploidy.** Duesberg P, Rausch C, Rasnick D, Hehlmann R III Genetic and phenotypic instability are hallmarks of cancer cells, but their cause is not clear. The leading hypothesis suggests that a poorly defined gene mutation generates genetic instability and that some of many subsequent mutations then cause cancer. Here we investigate the hypothesis that genetic instability of cancer cells is caused by aneuploidy, an abnormal balance of chromosomes. Because symmetrical segregation of chromosomes depends on exactly two copies of mitosis genes, aneuploidy involving chromosomes with mitosis genes will destabilize the karyotype. The hypothesis predicts that the degree of genetic instability should be proportional to the degree of aneuploidy. Thus it should be difficult, if not impossible, to maintain the particular karyotype of a highly aneuploid cancer cell on clonal propagation. This prediction was confirmed with clonal cultures of chemically transformed, aneuploid Chinese hamster embryo cells. It was found that the higher the ploidy factor of a clone, the more unstable was its karyotype. The ploidy factor is the quotient of the modal chromosome number divided by the normal number of the species. Transformed Chinese hamster embryo cells with a ploidy factor of 1.7 were estimated to change their karyotype at a rate of about 3% per generation, compared with 1.8% for cells with a ploidy factor of 0.95. Because the background noise of karyotyping is relatively high, the cells with low ploidy factor may be more stable than our method suggests. The karyotype instability of human colon cancer cell lines, recently analyzed by Lengnauer et al. [Lengnauer, C., Kinzler, K. W. & Vogelstein, B. (1997) Nature (London) 386, 623-627], also corresponds exactly to their degree of aneuploidy. We conclude that aneuploidy is sufficient to explain genetic instability and the resulting karyotypic and phenotypic heterogeneity of cancer cells, **independent of gene mutation.** Because aneuploidy has also been proposed to cause cancer, our hypothesis offers a common, unique mechanism of altering

water. Under the influence of estrogen, microtubules, for example, change their physical state and appear to dissolve. Experiments show that increasing amounts of estrogen cause progressively more severe disruptions of the mitotic apparatus, producing lopsided cell divisions. (When these abnormal "mitotic figures" are found in breast tissue, it means that cells are being killed by an excess of estrogen, but these dying cells are usually taken as "evidence of cancer.")

Biliverdin, produced along with carbon monoxide in the breakdown of heme, causes changes in other parts of the cytoskeleton, including the proteins in the nucleus which help to regulate the movements of nucleic acids.

Carbon monoxide, and other substances such as nitric oxide which also function as respiratory poisons, suppress energy production by the mitochondria, and this activates enzymes which cut DNA molecules, producing either DNA rearrangement, or apoptotic cell death.

All of these well established observations show the steps by which physiological reactions can lead to chromosomal and genetic abnormalities.

The steps toward cancer include chronic irritation, recognized for centuries as a cause of cancer; an inflammatory reaction activates enzymes that release estrogen. (Histamine, free fatty acids, prostaglandins, calcium and other products of inflammation are further promoted by estrogen, and synergize with it.)

Estrogen activates other inflammatory "acute phase" and stress-shock proteins, including heme oxygenase, which produces carbon monoxide and biliverdin. These are powerful protective and antioxidant factors making cells resistant to apoptosis and regulation.

Biliverdin (F. Paradisi, 1975) activates beta-glucuronidase, one of the main enzymes involved in the local release of estrogen.

In later stages, anemia and hemolysis are associated with CO and biliverdin production from the release of heme. (Anemia is seen in most patients with advanced cancer.) Biliverdin, combined with estrogen and hypoxia, alters the cytoskeleton, producing chromosome imbalances, causing mutations and activating the "oncogenes."

The respiratory defect of cancer interferes with the production of carbon dioxide. CO2 suppresses lactic acid formation, and is essential for all normal cell processes; it appears to be an important factor in producing cellular differentiation (Dictyostelium).

Estrogen promotes lactic acid formation, and promotes porphyrin synthesis, providing the material for forming heme and carbon monoxide. Besides causing porphyria, estrogen causes many other liver diseases, including cholestasis, the failure to release bile; the inhibition of carbon monoxide formation has been found to promote bile flow. Estrogen promotes the formation of the enzyme heme oxygenase, which forms carbon monoxide from heme.

Carbon monoxide increases the formation of cortisol, by stimulating ACTH release from the pituitary.

The stress response is self-sustaining on several levels. For example, stress increases the absorption of bacterial endotoxin from the intestine, which increases the estrogen level and synergizes with biliverdin and cortisol.

While estrogen does cause direct DNA damage, its clearest effect in carcinogenesis is on the cytoskeleton which regulates cell division, and defective cell division, rather than "gene mutation," is one of the important steps in the progression of cancer (Rubin, Duesberg).

Cancer cells are protected against the body's ability to destroy them, by the antioxidant functions of carbon dioxide and biliverdin..

The multilevel physiological nature of cancer calls for a multilevel physiological approach to its prevention and cure.

This would include antiestrogen regimes, antiinflammatory and antihistamine factors (histamine interacts closely with nitric oxide and carbon monoxide), adequate nutrition, carbon dioxide, and specific anti-carbon monoxide therapies (such as light, alcohol, and possibly the minerals which convert porphyrin into compounds that inhibit the production of carbon monoxide), and methods to decrease nitric oxide formation and to restrain cortisol production, since these promote the formation of carbon monoxide. **One of the most interesting approaches to inhibiting carbon monoxide production is to use vitamin B12, as hydroxocobalamin, as an antidote to nitric oxide, preventing the nitric oxide from stimulating the formation of heme oxygenase.** Wherever carbon monoxide mediates a biological malfunction, as in aquired immunodeficiency, Alzheimer's disease, and cancer, vitamin B12 seems to have a place as a detoxicant.

Progesterone and thyroid have several desirable properties that make them generally useful in cancer prevention and therapy. The shorter-chain saturated fatty acids contained in coconut oil have several beneficial effects. Aspirin and vitamin E

and simultaneously destabilizing normal cellular phenotypes.

Proc Natl Acad Sci U S A 1997 Dec 23;94(26):14506-11 **Aneuploidy correlated 100% with chemical transformation of Chinese hamster cells.** Li R, Yerganian G, Duesberg P, Kraemer A, Willer A, Rausch C, Hehlmann R Aneuploidy or chromosome imbalance is the most massive genetic abnormality of cancer cells. It used to be considered the cause of cancer when it was discovered more than 100 years ago. Since the discovery of the **gene,** the aneuploidy hypothesis has lost ground to the hypothesis that mutation of cellular genes causes cancer. According to this hypothesis, cancers are diploid and aneuploidy is secondary or nonessential. Here we reexamine the aneuploidy hypothesis in view of the fact that nearly all solid cancers are aneuploid, **that many carcinogens are nongenotoxic,** and that mutated genes from cancer cells **do not transform diploid human or animal cells.** By regrouping the gene pool-as in speciation-aneuploidy inevitably will alter many genetic programs. This genetic revolution can explain the numerous unique properties of cancer cells, such as invasiveness, dedifferentiation, distinct morphology, and specific surface antigens, much better than gene mutation, which is limited by the conservation of the existing chromosome structure. To determine whether aneuploidy is a cause or a consequence of transformation, we have analyzed the chromosomes of Chinese hamster embryo (CHE) cells transformed in vitro. This system allows (i) detection of transformation within 2 months and thus about 5 months sooner than carcinogenesis and (ii) the generation of many more transformants per cost than carcinogenesis. To minimize mutation of cellular genes, we have used nongenotoxic carcinogens. **It was found that 44 out of 44 colonies of CHE cells transformed by benz[a]pyrene, methylcholanthrene, dimethylbenzanthracene, and colcemid, or spontaneously were between 50 and 100% aneuploid.** Thus, aneuploidy originated with transformation. Two of two chemically transformed colonies tested were tumorigenic 2 months after inoculation into hamsters. The cells of transformed colonies were heterogeneous in chromosome number, consistent with the hypothesis that aneuploidy can perpetually destabilize the chromosome number because it unbalances the elements of the mitotic apparatus. Considering that all 44 transformed colonies analyzed were aneuploid, and the early association between aneuploidy, transformation, and tumorigenicity, we conclude that aneuploidy is the cause rather than a consequence of transformation.

Proc Natl Acad Sci U S A 1997 Sep 2;94(18):9614-9 **Dominant transformation by mutated human ras genes in vitro requires more than 100 times higher expression than is observed in cancers.** Hua VY, Wang WK, Duesberg PH The gene-mutation-cancer hypothesis holds that mutated cellular protooncogenes, such as point-mutated proto-ras, "play a dominant part in cancer," because they are sufficient to transform transfected mouse cell lines in vitro [Alberts, B., Bray, D., Lewis, J., Raff, M., Roberts, K. & Watson, J. D. (1994) Molecular Biology of the Cell (Garland, New York)]. However, in cells transformed in vitro mutated human ras genes are expressed more than 100-fold than in the cancers from which they are isolated. In **view of the discrepancy between the very low levels of ras transcription in cancers and the very high levels in cells transformed in vitro,** we have investigated the minimal level of human ras expression for transformation in vitro. Using point-mutated human ras genes recombined with different promoters from **either human metallothionein-IIA or human** fibronectin or from retroviruses we found dominant in vitro transformation of the mouse C3H cell line only with ras genes linked to viral promoters. These ras genes were expressed more than 120-fold higher than are native ras genes of C3H cells. The copy number of transfected ras genes ranged from 2-6 in our system. In addition, nondominant transformation was observed in a small percentage (2-7%) of C3H cells transfected with ras genes that are expressed less than 20 times higher than native C3H ras genes. Because over 90% of cells expressing ras at this moderately enhanced level were untransformed, **transformation must follow either a nondominant ras mechanism or a non-ras mechanism.** We conclude that the mutated, but normally expressed, ras genes found in human and animal cancers are not likely to "play a dominant part in cancer." The conclusion that mutated ras genes are **not sufficient or dominant** for cancer is directly supported by recent discoveries of **mutated ras in normal animals, and in benign human tissue, "which has little potential to progress" [Jen, J., Powell, S. M., Papadopoulos, N., Smith, K. J., Hamilton, S. R., Vogelstein, B. & Kinzler, K. W. (1994) Cancer Res. 54, 5523-5526]. Even the view that mutated ras is necessary for cancer is hard to reconcile with (i) otherwise indistinguishable cancers with and without** ras mutations, (ii) metastases of the same human cancers with and without ras mutations, (iii) retroviral ras genes that are oncogenic without point mutations, and (iv) human tumor cells having spontaneously lost ras mutation but not tumorigencity.

Proc Natl Acad Sci U S A 1990 Dec;87(24):10005-10009 **Physiological induction and reversal of focus formation and tumorigenicity in NIH 3T3 cells.** Rubin AL, Arnstein P, Rubin H. NIH 3T3 cells undergo morphological transformation in response to conditions of constrained growth, such as occur in low serum concentrations or at confluence. Transformation is expressed in a small fraction of the cells by the appearance of discrete foci of multiplying cells on a confluent monolayer of quiescent cells. We isolated and expanded cell populations from three dense and three light foci. Cells from each of these populations efficiently reproduced foci of the same morphotype when grown on a background of nontransformed NIH 3T3 cells. Using cultures derived from one of the dense foci (subline D/2), we found that the number of focus-forming units was stable and the cells remained tumorigenic when they were subjected to repeated thrice-weekly passage in 2% calf serum. However, equivalent passage in 10% calf serum

eventually rendered the cells incapable of both focus production and tumor formation. **The results show that the capacity to produce tumors as well as morphological transformation are produced as a response to physiological constraints of growth and/or metabolism in the absence of carcinogens and that both properties can be reversed by lifting the constraints. This behavior is typical of an adaptational response and, taken together with other supporting evidence, shows that tumorigenesis does not require conventional genetic alteration.** Published erratum appears in Proc Natl Acad Sci U S A 1991 Apr 15;88(8):3510

Cytobios 1975;12(45):13-18 **An inverse correlation (dose-response between 5-methyl-cytidine and the fate of spontaneous tumours in mice.** Strong LC, Matsunaga H Tumour-bearing mice, 248 in number, have been injected with 5-methyl-cytidine dissolved in physiological salt solution. The mice were divided into 5 series depending upon the amount of 5-methyl-cytidine they received. Mice of a successive series received 43.2, 28.8, 14.4 and 7.2 mg/kg body weight. There was a progressive increase in the percentage of mice showing regression of tumours in the successive series, as follows: 45%, 50%, 65%, 60%, and 67.8% respectively, giving an average percentage of regressions of 59.7%. The incidence of mice developing multiple primary tumours increased in the same successive series respectively as follows: 25%, 43.8%, 58.3%, 73.3%, and 70%, thus giving an average of 58.3%. The evidence obtained indicates an inverse correlation (dose-response) between the amount of the 5-methyl-cytidine injected and the percentage of regressions of spontaneous tumours.

J Surg Oncol 1975;7(5):367-373 **Further studies on a transmissible entity in relation to the control of cancer in mice.** Strong LC, Matsunaga H Tumor-bearing mice of the C3H/ST inbreds were used in this investigation. Of the 598 mice, 290 were controls, 248 received injections of 5-methyl cytidine dissolved in physiological salt solution, and 60 received injections of three nucleosides - adenosine, 6-methyl adenosine, and 5-methyl cytidine - also dissolved in physiological salt solution. The mice were divided into 6 groups based upon the number of generations of descent from a mouse injected with an alcohol-soluble liver extract. The criterion of tumor growth is the average increment of growth at the 20th observation period in the 7th week (3 per week). There is a cumulative inhibition of tumor growth, compared with controls, when 5-methyl cytidine is added to the effect of a transmissible entity which occurs in the lineal descendants of a tumor-bearing mouse injected with an alcohol-soluble liver extract and when the combination of three nucleosides in the same ratio of molar concentrations as in the liver extract is added to the effect of the transmissible entity.

J Surg Oncol 1975;7(6):531-534 **An inverse dose response of 5-methyl cytidine on multiple primary spontaneous tumors and their regressions in mice.** Strong LC, Matsunaga H Ten series mice of C3H/ST inbreds with spontaneous tumors have received 5-methyl cytidine (total 500 mice). Graded single doses of (1) 3.86, (2) 2.57, (3) 2.06, (4) 1.54, (5) 1.03, (6) 1.54, (7) 1.03, (8) 0.51, (9) 0.26, and (10) 0.13 mg/injection (three times weekly) were used. In series 1-5 the 5-methyl cytidine was dissolved in distilled water, and in series 6-10, the nucleoside was dissolved in physiological salt solution. In doses administered, series 4-5 overlapped with series 6-7. The number of mice that showed a regression of tumor increased in the successive series (48%-63% in series 1-5 and 25%-73% in series 6-10). As the number of mice with regressing tumors increased, the percentage of mice showing multiple primary tumors also increased. The administration of the nucleoside in physiological salt solution altered the inhibitory effect of 5-methyl cytidine on spontaneous tumors. For example, in physiological salt solution the 0.51 mg/injection gave as much inhibitory action as 1.03 mg/injection in distilled water. An inverse dose response is thus indicated between the amount of 5-methyl cytidine injected and the inhibition of spontaneous tumors in mice (percentage of regression and number of multiple primary spontaneous tumors are the criteria of inhibition considered).

Cytobios 1976;17(67-68):177-181 **A second method for induction of a transmissible entity in the control of cancer in mice.** Strong LC, Matsunaga H Spontaneous tumour-bearing mice of the C3H/St and subline C3HB/St inbred strains received injections of three nucleosides, adenosine, 6-methyl adenosine, and 5-methyl cytidine, prepared in the **same molecular concentration as they had occurred in an alcohol-soluble liver extract which in previous work had suppressed tumour growth.** Two transmissible entities appear to be present and they show different degrees of effect upon the growth and regression of spontaneous tumours of mammary gland origin (adenocarcinoma). The first transmissible entity (TE) occurred in the lineal descent of mice following injection of the liver extract. The second entity (TE2) appeared following injection of 5-methyl cytidine. TE manifested its maximum effect in suppressing cancer in mice during the 20th generation of a lineal descent following the injection of the original liver

extract into a mother of the cancer proband. TE2 appears to be optimal in controlling cancer in the F11 generation of a second lineal descent derived from an original cancer proband of the C3H/St inbred strain injected with 5-methyl cytidine.

J Surg Oncol 1977;9(1):99-103 **Increased effect of a transmissible entity on the control of cancer in C3 H/St mice.** Strong LC, Matsunaga HThree hundred and seventy-one mice of the C3H/St inbreds bearing spontaneous tumors of mammary gland origin have been used in this experiment. All mice studied were lineal descendents of a tumor-bearing mouse which had been injected with a liver extract. In this descent there appears to be a transmissible entity presumably induced by the injection of the liver extract. Following 15 generations of inbreeding after the appearance of a transmissible entity, a second sudden reversal of effect on cancer growth in mice has been indicated. This change has progressively altered the growth of cancer from a very low effect to a maximal effect, i.e., to a complete regression of a high percentage of the tumor. The maximal effect of the transmissible entity is the complete suppression of the growth of cancer during, at least, through the 25th period of observation, thus producing negative values of tumor growth. All these effects of the growth and fate of spontaneous tumors of mammary gland origin in mice have been obtained in a single lineal descent of C3H/St inbreds without resorting to any outcross.

Am J Physiol 1997 May;272(5 Pt 1):G1268-75. **Endogenous carbon monoxide suppression stimulates bile acid-dependent biliary transport in perfused rat liver.** Sano T, Shiomi M, Wakabayashi Y, Shinoda Y, Goda N, Yamaguchi T, Nimura Y, Ishimura Y, Suematsu M This study aimed to investigate whether carbon monoxide (CO), a product of heme oxygenase that degrades protoheme IX, serves as an endogenous modulator for biliary transport. To that end, effects of zinc protoporphyrin IX (ZnPP), a heme oxygenase inhibitor, on the biliary transport were tested in perfused rat liver. Perfusion of 1 microM ZnPP abolished detectable levels of CO in the venous perfusate and increased bile acid-dependent bile output accompanying an increased secretion of bile salts. The ZnPP-induced choleresis coincided with a reduction of tissue guanosine 3',5'-cyclic monophosphate (cGMP) levels and a decrease in vascular conductance. On administration of 2.5 microM CO, ZnPP-elicited choleresis, decreases in vascular conductance, and cGMP levels were all attenuated. Treatment with 1 microM 8-bromoguanosine 3',5'-cyclic monophosphate (8-BrcGMP) partly attenuated the **ZnPP-induced choleresis** in concert with repression of vascular conductance. Furthermore, treatment of the liver with methylene blue, a guanylate cyclase inhibitor, evoked a choleresis similar to that induced by ZnPP. **Thus endogenous CO suppression stimulates the biliary transport in part through a cGMP-dependent mechanism.**

Urology 1996 May;47(5):727-33 **Expression of heme oxygenase-1 (HSP32) in human prostate: normal, hyperplastic, and tumor tissue distribution.** Maines MD, Abrahamsson PA OBJECTIVES. Heme oxygenase isozymes, HO-1 and HO-2, are members of the stress/heat shock (HSP) family of proteins, with the known function of cleaving the heme molecule to biliverdin, iron, and carbon monoxide. The aim of this study was to examine the pattern of tissue expression of HO-1 in the humanprostate under different states of proliferation and differentiation and to investigate whether the pattern differs between these states. METHODS. Presently, we have determined the pattern of tissue expression of the stress-inducible isozyme, HO-1 (HSP32), in human prostate under normal and pathologic conditions, by immunohistochemistry, using polyclonal antibodies, and have measured HO-1 and HO-2 mRNA levels in normal prostate and benign prostatic hyperplasia (BPH) by Northern blotting. The activity of prostate to

catalyze heme degradation was also assessed. RESULTS. In normal and BPH tissue, columnar epithelial cells of acini and ducts and cells in stroma displayed HO-1 immunoreactivity; in all cells, perinuclear staining was prominent. In BPH tissue, however, a more intense staining of the epithelial cells occurred, with notable staining of the basal cells. In undifferentiated malignant tumors, intense HO-1 staining was manifest in nearly all tumor cells, and also in the epithelial lining of blood vessels. HO-1 in the prostate tissue was found catalytically active and oxidatively cleaved the heme molecule (Fe-protoporphyrin IX) to biliverdin. Northern blot analysis shows that two forms of HO are present in the human prostate. Compared with normal tissue, predominantly hyperplastic tissue demonstrates a pronounced increase in the approximately 1.8 kb mRNA that hybridizes to the rat HO-1 probe. The levels of two transcripts, approximately 1.3 and approximately 1.7 kb, that hybridize to the rat HO-2 probe are not increased in BPH tissue. CONCLUSIONS. **The finding that HO-1 expression is increased in BPH and malignant prostate tissue is consistent with a role for this stress protein in the pathogenesis of BPH and prostate cancer; in the context of iron metabolism, an argument is made in support of this possibility.**

Cancer Res 1991 Feb 1;51(3):974-8 **Induction of heme oxygenase: a general response to oxidant stress in cultured mammalian cells.** Applegate LA, Luscher P, Tyrrell RM. Accumulation of heme oxygenase mRNA is strongly stimulated by treatment of cultured human skin **fibroblasts with ultraviolet radiation, hydrogen peroxide, or the sulfhydryl reagent sodium arsenite (S. M.** Keyse and R. M. Tyrrell. Proc. Natl. Acad. Sci. USA, 86: 99-103, 1989). Since this will result in a transient reduction in the prooxidant state of cells, the phenomenon may represent an important inducible antioxidant defense mechanism. To examine the generality of the response, we have measured the accumulation of the specific mRNA in a variety of human and mammalian cell types after inducing treatments. Induction by sodium arsenite is observed in all additional human cell types tested. This includes primary epidermal keratinocytes and lung and colon fibroblasts as well as established cell lines such as HeLa, TK6 lymphoblastoid, and transformed fetal keratinocytes. Strong induction of heme oxygenase mRNA is also observed following sodium arsenite treatment of cell lines of rat, hamster, mouse, monkey, and marsupial origin. The agents which lead to induction in cultured human skin fibroblasts fall into two categories: (a) those which are oxidants or can generate active intermediates (ultraviolet A radiation, hydrogen peroxide, menadione, and the tumor promoter, 12-O-tetradecanoylphorbol-13-acetate); (b) agents which are known to interact with or modify cellular glutathione levels (buthionine sulfoximine, sodium arsenite, iodoacetamide, diamide, and cadmium chloride). These observations strongly support the hypothesis that induction of the enzyme is a general response to oxidant stress in mammalian cells and are consistent with the possibility that the cellular redox state plays a key role.

Carcinogenesis 1992 Feb;13(2):227-32 **Endogenous glutathione levels modulate both constitutive and UVA radiation/hydrogen peroxide inducible expression of the human heme oxygenase gene.** Lautier D, Luscher P, Tyrrell RM Swiss Induction of the expression of the mammalian heme oxygenase gene appears to be a general response to oxidant stress. In view of the role of glutathione in protecting cells against solar UVA radiation and other forms of oxidant stress, we have investigated the relationship between intracellular glutathione levels and the inducibility of the human heme oxygenase gene after treatment of populations of cultured skin fibroblasts with either UVA radiation or hydrogen peroxide. We observe a clear relationship between cellular glutathione status and both the constitutive and oxidant-inducible accumulation of heme oxygenase mRNA. Glutathione depletion may lead to enhanced gene expression either as a result of the potentiated accumulation of active oxygen intermediates or as a result of the direct influence of glutathione on a critical target involved in signal transduction.

Bull Cancer 1990;77(5):479-83 **[Modification of the cellular cytoskeleton and hepatic tumor promotion].** [Article in French] Decloitre F, Martin M, Ouldelhkim M, Nizard C. Non transformed epithelial hepatic cells (established cell line and adult rat hepatocytes) treated by liver **tumor promoters, phenobarbital and biliverdin,** for 24 and 48 h showed a fragmentation and loss of F-actin and a depolymerisation of microtubules. This pattern closely resembles that of transformed cells which were not susceptible to the action of promoters. In liver preneoplastic nodules obtained from rats submitted to an initiation-promotion process, actin almost completely disappeared with the concomitant appearance of a characteristic enzymatic pattern rich in GGT and GST-P. Therefore, cytoskeleton of hepatic cells is a target for tumor promoters and could play a role in promotion mechanism.

J Biochem (Tokyo) 1997 Jun;121(6):1162-8 **Possible implications of the induction of human heme oxygenase-1 by nitric oxide donors.** Takahashi K, Hara E, Ogawa K, Kimura D, Fujita H, Shibahara S. To explore the involvement of nitric oxide (NO) in the induction of heme oxygenase-1, an essential enzyme in heme catabolism, we studied the effects of NO donors on the expression of heme oxygenase-1 **mRNA in HeLa human cervical cancer cells. Treatment with each of three NO donors, sodium nitroprusside, 3-morpholinosydnonimine, and S-nitroso-L-glutathione, caused noticeable increases in**

the expression levels of heme oxygenase- mRNA, but not heme oxygenase-2 mRNA. On the other hand, nitrite or 8-bromo cGMP exerted no noticeable effect on the levels of heme oxygenase-1 mRNA. We showed that sodium nitroprusside also increased the **levels of heme oxygenase-1 protein.** The sodium nitroprusside-mediated increase in heme oxygenase-1 mRNA levels was abolished by treatment with actinomycin D. The expression levels of heme oxygenase-1 mRNA were also **increased by NO donors in human melanoma and neuroblastoma cell lines.** Thus, the observed induction of heme oxygenase-1 may represent an important response to NO or NO-related **oxidative stress.** The half lives of heme oxygenase-1 and heme oxygenase-2 mRNAs were estimated to be about 3.2 h and more than 5 h, respectively.

Steroids, 1998, 63(5-6):252-6, **Neuroendocrine mechanisms underlying the control of gonadotropin secretion by steroids.** Mahesh VB, Brann DW. There is considerable evidence that although estradiol may trigger the preovulatory surge of gonadotropins, progesterone is required for its full magnitude and duration and that glucocorticoids bring about selective follicle-stimulating hormone release. The luteinizing hormone-releasing hormone (LHRH) neuron does not have steroid receptors and is regulated by excitatory amino acid neurotransmission. **Steroids do not appear to modulate excitatory amino acid receptors directly but increase release of glutamate in the preoptic area. This may be due to the suppression by steroids** of the enzyme glutamatic acid decarboxylase67 that converts glutamate into GABA. NMDA receptors colocalize with nitric oxide synthase-containing neurons that surround the LHRH neurons in the preoptic area and intersect the LHRH fibers in the median eminence. Other potential novel pathways of LHRH release that are currently being explored include carbon monoxide generated by the action of heme oxygenase-2 on heme molecules and bradykinin acting via bradykinin B2 receptors.

Biochem Biophys Res Commun 1997 Dec 18;241(2):215-20 **Involvement of the heme oxygenase-carbon monoxide pathway in keratinocyte proliferation.** Clark JE, Green CJ, Motterlini R. It has been suggested that nitric oxide (NO), a small gaseous molecule with a multiplicity of cellular functions, plays an important part in the regulation of cellular proliferation. We have examined the effect of the NO donor sodium nitroprusside (SNP) on heme oxygenase-1 (HO-1) expression in human **epidermal keratinocytes and investigated the contribution of the heme oxygenase pathway in the control of** keratinocyte proliferation. Incubation of keratinocytes with 0.5 mM SNP resulted in a **2.5-fold increase in heme oxygenase activity which was reflected by a significant increase in HO-1** protein expression, as measured by Western blot. This effect was associated with a **200% increase in keratinocyte proliferation.** The proliferative effect of the NO donor was totally abolished by co-incubation of SNP with tin protoporphyrin IX, a potent inhibitor of heme oxygenase, or hydroxocobalamin, a NO scavenger. These results suggest that the heme oxygenase pathway is involved in keratinocyte proliferation mediated by NO.

J Neuroimmunol 1998 Jun 1;86(1):104-9 **Endotoxin stimulates an endogenous pathway regulating corticotropin-releasing hormone and vasopressin release involving the generation of nitric oxide and carbon monoxide.** Kostoglou-Athanassiou I, Costa A, Navarra P, Nappi G, Forsling ML, Grossman AB.

Ann N Y Acad Sci 1998 May 1;840:249-61 **Acute and subacute effects of endotoxin on hypothalamic gaseous neuromodulators.** Kostoglou-Athanassiou I, Jacobs RA, Satta MA, Dahia PL, Costa A, Navarra P, Chew SL, Forsling ML, Grossman AB.

Cell Biol Toxicol 1990 Jan;6(1):23-34 **Modifications of microfilaments and microtubules induced by two hepatic tumor promoters, phenobarbital and biliverdin in non-transformed and transformed hepatic cell lines.** Decloitre F, Lafarge-Frayssinet C, Martin M, Frayssinet C. "Microfilaments and microtubules are components of the cytoskeleton which could be implicated in neoplastic transformation. We studied the effect of **two hepatic tumor promoters, phenobarbital (PB) and biliverdin** (BV), on microfilaments and microtubules of non-transformed (Cl3) and transformed (FV) hepatic epithelial cells. Cl3 non-transformed cells cultured in the presence of I X 10(-6) M BV for 48 h showed a loss of F-actin, fragmentation of actin and the appearance of star-like structures in the cytoplasm, as well as loosening of the peripheral bundle of actin, and some ruffling of cell membranes." "BV and PB also produced in these cells modifications of microtubules characterized by a disappearance of centrosome staining in numerous cells, a condensed ring of tubulin around the nucleus and a depolymerized aspect of the microtubular network. All these modifications of microfilaments and microtubules closely resembled those observed in FV transformed cells in the absence of any treatment (Solvent DMSO only). We did not observe an effect of BV and PB on FV cells. The present data demonstrate that the cytoskeleton of non-transformed epithelial liver cells is sensitive to the action of liver tumor promoters suggesting that it might play a role as to yet be defined in the promotion mechanism. "

Bull Cancer 1990;77(5):475-8 **[Oncogenes and tumor promotion].** [Article in French] Lafarge-Frayssinet C, Frayssinet C. We have studied the effects of 2 hepatic promoters: an exogenous one:phenobarbital, and an endogenous **one biliverdin (a bile pigment) on the expression of 3 oncogenes c-Ki-ras, c-fos and c-myc involved in**

growth process, differentiation and tumorigenesis for the liver. This work was done: 1) in vitro using epithelial liver cell strains originated from 10-day old rats; 2) in vivo using regenerating liver after partial hepatectomy, as well as preneoplastic nodules obtained by the Solt and Farber procedure. In all cases we have shown an important overexpression of the oncogenes.

Cell Mol Biol 1981;27(2-3):77-82 **Enhancement of DNA synthesis by biliverdin in a non-transformed liver cell strain.** Lafarge-Frayssinet C, Morel-Chany E, Trincal G, Frayssinet C Cancer Lett 1983 Apr;18(3):277-82 **Promoting effect of biliverdin for liver cells initiated by aflatoxin B1.** Lafarge-Frayssinet C, Morel-Chany E, Trincal G, Frayssinet C In this paper we have studied the participation of biliverdin, a bile pigment produced from hemoglobin catabolism, in a two-stage carcinogenesis model using hepatic cells in culture. The initiation was realised by a short term exposure to low doses of aflatoxin B1. The cells were then cultivated in the presence of biliverdin in the medium. We observed that biliverdin increased the rate and the efficiency of neoplastic transformation of cells. **These results suggest that biliverdin may act as a promoting substance.**

Cancer Lett 1989 Mar;44(3):191-8 **Over expression of proto-oncogenes: ki-ras, fos and myc in rat liver cells treated in vitro by two liver tumor promoters: phenobarbital and biliverdin.** Lafarge-Frayssinet C, Frayssinet C Among the liver cell strains established in the laboratory from the liver of 10-day-old rats, some of them (FV) underwent spontaneous neoplastic transformation after a number of subcultures. However, one (Cl3) had maintained a non-transformed phenotype (persistence of contact inhibition, lack of growth in soft agar and of gamma glutamyltranspeptidase activity). These cells were grown either for a short time (48 h) or a longer time (3 weeks) in the presence of two liver tumor promoters: phenobarbital (0.2 x 10(-3) M) or biliverdin (10(-6) M). Total RNA was analysed by dot blot and Northern blot, then hybridized with ki-ras, fos and myc probes, previously labelled with 32P by nick translation. The three oncogenes were well expressed by the two strains but while an over-expression was observed for the Cl3 non-transformed cells when they were grown in presence of phenobarbital or biliverdin, the FV-transformed cells were not sensitive to the two promoters.

Pathol Biol (Paris) 1975 Feb;23(2):101-5 **A cytochemical study of some enzyme activities in biliverdin-treated cell cultures.** Paradisi F, Graziano L, de Ritis F The authors studied the modifications of the activities of some enzymes in cell cultures submitted to the action of biliverdin. This biliary pigment rapidly induces a **remarkable increase in alkaline phosphatase and ATP-ase activities and subsequently, an activation of acid phosphatase and beta-glucuronidase.** On the contrary, 5'-nucleotidase and glucose-6-phosphatase activities remain unchanged. These results are discussed and compared with those obtained in our and other laboratories by using unconjugated bilirubin on different biological substrates.

Mol Pharmacol 1997 Oct;52(4):590-9 **Aryl hydrocarbon receptor-dependent induction of cyp1a1 by bilirubin in mouse hepatoma hepa 1c1c7 cells.** Sinal CJ, Bend JR "Heme metabolism normally involves enzymatic conversion to biliverdin and subsequently to bilirubin, catalyzed by heme oxygenase and biliverdin reductase, respectively. We examined the ability of exogenously added hemin, biliverdin, or bilirubin to regulate Cyp1a1, an enzyme that may be active in bilirubin elimination. A substantial dose-dependent increase in Cyp1a1 mRNA occurred after treatment of Hepa 1c1c7 cells with either of the three compounds. This increase was readily apparent 1 hr after treatment with biliverdin or bilirubin but required >/=2 hr with hemin." "These data indicate that bilirubin induces Cyp1a1 gene transcription through direct interaction with the AHR. In contrast, hemin **and biliverdin seem to induce Cyp1a1 indirectly by serving as precursors to the endogenous formation of bilirubin via normal heme metabolism pathways. This is the first direct demonstration that the endogenous heme metabolite bilirubin can directly regulate Cyp1a1 gene expression and enzymatic activity in an AHR-dependent manner."**

J Biochem (Tokyo) 1997 Jun;121(6):1162-8 **Possible implications of the induction of human heme oxygenase-1 by nitric oxide donors.** Takahashi K, Hara E, Ogawa K, Kimura D, Fujita H, Shibahara S To explore the involvement of nitric oxide (NO) in the induction of heme oxygenase-1, an essential enzyme in heme catabolism, we studied the effects of NO donors on the expression of heme oxygenase-1 **mRNA in HeLa human cervical cancer cells. Treatment with each of three NO donors, sodium nitroprusside, 3-morpholinosydnonimine, and S-nitroso-L-glutathione, caused noticeable increases in the expression levels of heme oxygenase- mRNA, but** not heme oxygenase-2 mRNA. On the other hand, nitrite or 8-bromo cGMP exerted no noticeable effect on the levels of heme oxygenase-1 mRNA. We showed that sodium nitroprusside also increased the **levels of heme oxygenase-1 protein.** The sodium nitroprusside-mediated increase in heme oxygenase-1 mRNA levels was abolished by treatment with actinomycin D. The expression levels of heme oxygenase-1 mRNA were also **increased by NO donors in human melanoma and neuroblastoma cell lines.** Thus, the observed induction of heme oxygenase-1 may represent an important response to NO or NO-related **oxidative stress.** The half lives of heme oxygenase-1 and heme oxygenase-2 mRNAs were estimated to be about 3.2 h and more than 5 h, respectively.

Ann N Y Acad Sci 1998 May 1;840:249-61 **Acute and subacute effects of endotoxin on hypothalamic gaseous neuromodulators.** Kostoglou-Athanassiou I, Jacobs RA,

Satta MA, Dahia PL, Costa A, Navarra P, Chew SL, Forsling ML, Grossman AB.

Biokhimiia 1987 Sep;52(9):1501-11 **[Activation of lipolysis and ketogenesis in tumor-bearing animals as a reflection of chronic stress states].** [Article in Russian] Chekulaev VA, Shelepov VP, Pasha-zade GR, Shapot VS In order to elucidate the peculiarities of brain metabolism in tumour-bearing organisms, the arterio-venous (A-V) content of glucose, acetoacetate (Ac-Ac), beta-hydroxybutyrate (beta-HB) and non-esterified fatty acids (NEFA) in growing Zajdela ascite hepatoma (ZAH) and solid hepatoma 27 (H-27) was compared. Analysis of metabolic patterns of healthy, starving and fed recipients (ZAH and H-27) revealed the inadequacy of the concepts on anorexia as being the cause of carbohydrate-lipid metabolic disturbances. In tumour-bearing organisms **lipolysis and ketogenesis reflect the tumour-induced chronic stress.** Absorption of beta-HB and release of Ac-Ac by brain were observed at all stages of malignant growth. **This is probably due to a partial switch-over of brain metabolism to non-carbohydrate energy sources.** Besides, certain stages of tumour growth are associated with **active assimilation of NEFA by brain.** A correlation between the A-V difference with respect to glucose and Ac-Ac as well as between the glucose and NEFA contents was established. It was assumed that the A-V difference in glucose is the main regulator of ketone body metabolism.

Arkh Patol 1987;49(6):10-8 **[Combination of immunodepression and disorders in nucleic acid metabolism of lymphoid tissue as a manifestation of a paraneoplastic syndrome].** [Article in Russian] Potapova GI, Shapot VS Several physiological, biochemical, and molecular biological approaches to the study of factors determining immunodepression in tumor-bearing animals are considered. Cancer cells release substances of nucleic and peptide nature that suppress the functional activity of macrophages and lymphocytes and stimulate cell proliferation in organs and tissues of the host. Suppressor T cells capable of inhibiting the function of helper T cells and impairing the differentiation of killer T cells are activated. The suppression **of T- and B-cell-mediated immunity in the tumor host involves disturbances of nucleic acid metabolism in those cells as well as hypersecretion of glucocorticoids.** The impairments of lymphocyte proliferation and differentiation that result in reduced immune responsiveness are attributable to drastic alterations in the metabolism of purine and pyrimidine nucleotides and to the damage sustained by the lymphocyte's DNA.

Eksp Onkol 1987;9(6):62-7 **[Relation between disorders of glucose metabolism, secretion of somatotropic hormone, thyroxine, thyrotropin and hematocrit indices in rats with transplanted hepatomas].** [Article in Russian] Shelepov VP, Pasha-zade GR, Chekulaev VA, Shapot VS **The levels of growth hormone (GH) in the blood of rats with ascite Zajdela hepatoma and hepatoma 27 (H-27) are shown to increase during the tumour growth. Stimulation of the GH secretion is a result of the hypoglycaemic stress.** An increase in the blood GH secretion is also observed in the fasting rats. To reveal the **predominance of catabolic GH effects over the anabolic ones** in the tumour host determination of the molar insulin/GH ratio in the blood is suggested. A direct correlation is found between reduction of this index, glycaemia and the content of liver glycogen. A short-term induced hyperglycaemia evokes a paradoxical reaction in terms of GH secretion. In contrast to control fasting rats, in tumour-bearing animals no **correlation between thyrotropin and thyroxine blood concentration could be observed. Anaemia increasing progressively in the course of the tumour growth may be the cause of the above phenomenon.**

J Neuroendocrinol 1998 Oct;10(10):793-802 Influence of carbon monoxide, and its interaction with nitric oxide, on the adrenocorticotropin hormone response of the normal rat to a physico-emotional stress. Turnbull AV, Kim CK, Lee S, Rivier CL "We determined whether the gas carbon monoxide (CO) altered the adrenocorticotropin hormone (ACTH) response to mild inescapable electrofootshocks, and whether it interacted with nitric oxide (NO). Peripheral injection of the NO synthase (NOS) inhibitor Nomeganitro-L-arginine-methylester (L-NAME), a compound which readily crosses the blood-brain barrier, produced the expected blunting of the ACTH response to the shocks. This effect was mimicked by other arginine analogues such as L-nitroarginine (L-NNA) and NG-methyl-L-arginine (NMMA). The subcutaneous (s.c.) administration of the heme oxygenase (HO) blockers tin mesoporphyrin (SnMP) or tin protoporphyrin (SnPP) significantly decreased brain HO levels, indicating that both compounds had penetrated the brain." "SnMP and SnPP both decreased shock-induced ACTH release, though the magnitude of this effect was slightly less than that of L-NAME. The influence of SnPP was further augmented in rats with concomitant blockade of NO formation, which suggests that both NO and CO are necessary for the full response of this axis to electrofootshocks. Finally, the ability of SnPP to significantly blunt the expression of the mRNA for the immediate early gene NGFI-B in the paraventricular nucleus (PVN) of rats exposed to shocks, indicates that the influence of CO was exerted on hypothalamic neuronal activity. Collectively, our results show that NO and CO exert a **stimulatory effect on the HPA axis response to mild electrofootshocks, and that at least part of this influence takes place on hypothalamic neurons and/or their afferents."**

J Neurochem 1994 Sep;63(3):953-62 **Corticosterone regulates heme oxygenase-2 and NO synthase transcription and protein expression in rat brain.** Weber CM, Eke BC, Maines MD Heme oxygenase (HO)-1 and -2 produce carbon monoxide, which is suspected, as is nitric oxide (NO), to function as a neuronal messenger. We report on glucocorticoid-mediated modulation of HO-2 and NO synthase expression in brain and the differential response of the two proteins to corticosterone in different brain regions. Corticosterone treatment (40 mg/kg, 20 days) had opposing effects on HO-2 and NO synthase transcript levels:

increasing the 1.3- and 1.9-kb HO-2 mRNAs and decreasing that of the brain-specific 10.5-kb NO synthase. Corticosterone did not uniformly affect HO-2 protein expression in all regions, but appeared to cause a universal reduction in NO synthase, e.g., HO-2 was decreased in hippocampus (CA1 and dentate gyrus), but not in cerebellum. In contrast, NADPH diaphorase staining was reduced in hippocampus and in molecular and granule layers of cerebellum (not detected in Purkinje cells). **Striking deficits in neuronal morphology and number of diaphorase-staining neurons were observed in the lateral tegmental area, paraventricular nucleus, and frontal cortex; HO-2 expression was only selectively affected. In cerebellum, activity of NO synthase, but not that of HO, was reduced. Consistent with the possibility that carbon monoxide can generate cyclic GMP, the change in cyclic GMP level did not mirror the decrease in NO synthase. We suggest that glucocorticoid-mediated deficits in hippocampal functions may reflect their negative effect on messenger-generating systems.**

Acta Oncol 1995;34(3):329-34 **Relationship between tumour oxygenation, bioenergetic status and radiobiological hypoxia in an experimental model.** Nordsmark M, Grau C, Horsman MR, Jorgensen HS, Overgaard J. "Tumour oxygenation and bioenergetic status were measured in the same tumour and these results related to radiobiological hypoxia. A C3H mouse mammary carcinoma grown in the feet of CDF1 mice was used." "In conclusion, oxygen electrode measurements were sensitive to changes in tumour hypoxia whereas **the bioenergetic status alone seemed to be a less precise measure of hypoxia** in this tumour model. Furthermore, the present study demonstrated that tumour cells in vivo can actually maintain the bioenergetic status during a period of severe hypoxia."

Mutat Res 1998 May 25;400(1-2):439-46 **Mutagenesis induced by the tumor microenvironment.** Yuan J, Glazer PM **"Genomic instability is a commonly observed feature of tumors. Most investigations addressing the mechanism of tumor progression have focused on the genetic factors that may play a role. Growing evidence now suggests that, in addition to these endogenous factors, the exogenous environment within solid tumors may by itself be mutagenic and constitute a significant source of genetic instability. The tumor microenvironment is characterized by regions of fluctuating hypoxia, low pH, and nutrient** deprivation. Each of these microenvironmental factors has been shown to cause severe disturbance in cell metabolism and physiology. Both in vivo and in vitro data demonstrate that exposure of tumor cells to **adverse conditions can directly cause mutations, contributing to genetic instability. In this review, we will reexamine the current body of evidence on the role of the tumor microenvironment in inducing mutagenesis and consequent tumor progression."**

Lakartidningen 1995 May 24;92(21):2197-2198 **[Estrogen treatment caused acute attacks of porphyria].** [Article in Swedish] Wetterberg L, Olsson MB, Alm-Agvald I. Two female patients with acute intermittent porphyria, who received oestrogen skin pads as supplementary treatment for postmenopausal discomfort, developed severe psychiatric disorders with persistent confusion, aggression and paranoid reactions. Some decades earlier they had reacted with symptoms of acute porphyria following oral contraceptive usage. There is well documented evidence of the advisability of restrictiveness in the use of oestrogens in conjunction with acute porphyria, particularly in cases of patients with a history of hormone-related symptoms of acute porphyria. The putative mechanisms by means of which oestrogens may exert effects on neurotransmitters and peptides are discussed in the article. The authors would be grateful to hear from colleagues abroad who have treated patients with similar symptoms following postmenopausal treatment with oestrogens.

J Am Acad Dermatol 1994 Aug;31(2 Pt 2):390-392 **Porphyria cutanea tarda: pregnancy versus estrogen effect.** Urbanek RW, Cohen DJ Department of Medicine, Staten Island University Hospital, NY 10305. We describe the worsening of porphyria cutanea tarda in a young woman while she was taking oral contraceptives. However, she did not have an exacerbation during two pregnancies. We conclude that estrogens produced during pregnancy do not exert the same effect as orally administered medications that contain estrogen. The pronounced effect of oral ethinyl estradiol on the liver may be attributed to its first-pass effect on that organ.

Int J Radiat Oncol Biol Phys 1998 Nov 1;42(4):849-53 **The comparative effects of the NOS inhibitor, Nomega-nitro-L-arginine, and the haemoxygenase inhibitor, zinc protoporphyrin IX, on tumour blood flow.** Tozer GM, Prise VE, Motterlini R, Poole BA, Wilson J, Chaplin DJ.

Progesterone and ideas of "balance" in "hormone replacement therapy": The importance of inhibition

Because I came to progesterone research after involvement in other biological issues such as the study of the effects of nuclear fallout and ionizing radiation on the brain, rather than as a physician, I had no commitment to any of the ideas which had grown up with the pharmaceutical industry, and that have become so basic to the professions' understanding of the actions of drugs and hormones. For example, *receptors* are supposed to be part of our genetic constitution, making us able to respond to drugs, poisons, hormones, infections, allergens, nervous stimuli, odors, etc. A substance, by binding to its receptor, sets in motion a biological response. With stimuli such as odors and adrenalin, there is a certain logic to the situation—with prolonged stimulation, fatigue sets in, we adapt to a certain level of stimulation, and it then takes a larger amount of the stimulus to produce a response. The receptors are "desensitized."

But if a stimulus evoked, or increased the quantity of, its own receptor, *increasing* the tissue's sensitivity, there would be a tendency for things to get out of control. What could be the biological meaning of such a situation?

Imagine applying this principle to various kinds of receptors—any odor would tend to increase until it became overpowering, the heart would be accelerated by smaller and smaller stimuli, or would require stronger and stronger impulses from the vagal nerve to restrain it. **Allergy represents what happens when a stimulus creates increased sensitivity to itself;** autoimmunity and lymphoma could represent similar processes of positive-feedback, increasing responses to a given level of stimulation. Excitotoxicity, epilepsy, movement disorders, and mania are other examples of what happens when negative (inhibitory) feedback fails. (Estrogen's interactions with other excitatory processes, such as allergy, will be considered in other articles; see Kalogeromitros, et al., 1995; Ahmed, et al., 1989.)

Estrogen's action on many tissues increases the tissue's ability to bind estrogen; estrogen induces its own "receptor," in a self-stimulating, self-destabilizing process. This is unlike the behavior of other "receptors," such as the adrenalin receptor, which is inactivated by increased exposure to adrenalin. This unusual interaction between tissue and hormone requires careful examination.

For example, estrogen's immediate effect on a responsive tissue is to cause it to take up water, and to increase its ratio of sodium to potassium; these changes lead to depolarization-activation of nerve, muscle, and some glandular cells, and of initiation of growth and cell division in other cell types. If the stimulation to growth process continued unchecked, or even accelerated, it's obvious that form and proportion and organization would quickly be lost. Similarly with the other forms of stimulatiion—activated responses must not continue beyond the organism's need for them.

Estrogenic stimulation, like an allergic reaction, would tend to increase progressively, if it weren't for the antiestrogens. The antiinflammatory effect of the glucocorticoids on an allergic reaction, preventing anaphylactic shock, are analogous to the effects of the antiestrogens, blocking estrogenic stimulation. The analogy is especially interesting, when we consider that Selye characterized estrogen's effect as similar to the shock phase of the stress reaction, and that antihistamines are generally

Hirsutisme = ↑ actw ↑ stimu surre
l'efficacité de la réponse (2 inhibition) face à la stimu est très importante

antiestrogenic, and antiestrogens are generally antihistaminic.

Since the actual levels of estrogen increase (Musey, et al., 1987; also see Rodriguez, et al., 1993 and O'Rourke, et al., 1996) during a woman's reproductive years, and then often act almost unopposed during a time around menopause (Nencioni and Polvani, 1985), and tend to increase progressively in aging men, and in both sexes during stress, we need to know what our protective systems are, for interrupting estrogen's excitatory actions on a great variety of tissues.

(1) One of progesterone's effects is to degrade and eliminate estrogen receptors (Brown and MacLusky, 1994; Medlock, et al., 1994; Okulicz, et al., 1993; Selcer and Leavitt, 1988). This is clearly an antiestrogenic action, and many people like to say the opposite, that progesterone induces estrogen receptors, simply because the idea suits their their doctrines of synergy, balance, and more basic ideas of genetic constitution, the nature of gender, etc. But the facts are so clear that they will have to look elsewhere for something to support their orientation.

(2) Recently it has been found that estrogen receptors are degraded by proteasomes (Nawaz, et al., 1999; Alarid, et al., 1999). This could relate to the fact that unsaturated fatty acids promote the retention of estrogen in the cell, since unsaturated fatty acids often inhibit proteolytic enzymes.

(3) By reducing the cell's ability to bind estrogen, progesterone acts as an "estrogen repellant." But

(4) it also activates enzymes* which physically/chemically detoxify estrogen, converting it to a water-soluble sulfated form, in which it tends to be expelled from cells and to be excreted in the urine.

(5) On the systemic level, progesterone helps to activate the liver's detoxifying systems, in which other types of enzymes modify estrogen, reducing its activity and preparing it for excretion, in both the bile and the urine.

One way of looking at progesterone is that it is an antiestrogen. The estrogen industry doesn't like that concept, and prefers to think of progesterone as an estrogen *synergist*. But if its effect is to interrupt estrogen's excitatory actions, and to eliminate estrogen from the tissues, it is no more "synergic" with estrogen than the inhibitory impulses of the vagus nerve are synergic with the excitatory adrenergic influences. The FDA, in its service to industry, has classified progesterone as a "progestin," defining the category only in terms of an effect on the uterus. No other pseudo-scientific concept exceeds this in its harmful consequences.

But to describe progesterone as an antiestrogen is meaningful only to the extent that we understand the nature of estrogenic stimulation.

Estrogen, as an easy derivative of testosterone, is deeply involved in the establishment of masculine features; even in mature women, estrogen excess (progesterone deficiency) can produce hirsutism and other masculine traits when it overstimulates the adrenal glands. As a goad (the term estrogen is based on *estrus*, gadfly, intense stimulus, goad), estrogen initiates activity in cells and systems; depending on the organism's resources, that stimulus will be restrained before it gets out of control.

Does the specific outcome of stimulation take its direction from estrogen, or rather from the ways in which estrogen is neutralized and detoxified? There are many antiestrogenic systems (e.g., thyroid, progesterone, testosterone, sulfation, methylation, glucuronidation, antiinflammatory factors, etc.) and the varied, specific nature of the organism's response to stimulation is probably sufficient to account for the different outcomes, such as masculinity or feminity, tumefaction or growth, alertness or mania.

How specific is estrogenic stimulation itself? Asphyxia, radiation injury, vitamin deficiencies, and other harmful stimuli, closely mimic the estrogenic excitation/shock response. (Boling, et al., 1939;Mandl and Zuckerman, 1956; Biskind, 1946.) Estrogenic activation, with the uptake of water and the loss of potassium (relative to intracellular sodium), is probably the simplest reaction a cell is capable of, and any specificity that can be found in the process is the result of pre-existing cellular conditions, or of defensive reactions of the organism. **Depending on its place in the life of an individual, estrogen can either masculinize or feminize, produce breasts or whiskers.**

Estro ↑ = ↑ H2o ↑ Na+ Intracell ↓ K+ intracell

Allergic Shock = ↑ histamine ↑ glucocor ↑ mucus

Hydration cellular important

The similarity of radiation injury to estrogenic stimulation has led to studies showing some radiation protection from progesterone; similar protective actions of progesterone can be seen for other types of injury. Thyroid, and other antiestrogens, also have a wide spectrum of protective actions, against radiation, asphyxia, carcinogens, etc.

I think the only way to approach the *general nature* of cellular excitation is to see it in terms of the basic properties of the living material. Only something as general and basic as the cell's state of hydration, its "wetness," can account for the coherent way in which cells are activated, with related processes happening at all levels, from chromosomes, to mitochondria and enzymes, the structural protein meshwork of the cytoskeleton, and sensory functions.

Cells use something like metaphor or analogy (as previously discussed in relation to J. Cairns' work, and e.g., in observations such as those of Smith, et al., 1990) to achieve coordination over long distances, and a medium of coordination and cooperation is needed; cell water, with its rich structural potential, provides that medium.

What do these perspectives imply for medical practice?

First, that the issue of "estrogen defiiciency" must be weighed very carefully. 35 years ago, men were given estrogen "to protect them from heart attacks," and the treatment increased the incidence of heart problems; several new campaigns are underway to use estrogens to protect both men and women from heart attacks. The arguments for "cardioprotective" actions of estrogen are based on very peculiarly chosen "indicators," excluding from consideration estrogen's contributory role in diabetes, elevation of free fatty acids and triglycerides, in the tendency to clot, synergism with adrenalin in spasticity of blood vessels, and other conditions relevant to heart disease. Similar campaigns, contrary to facts, are being developed in "brain protection," and other imaginary benefits of estrogen. Consistently, it has been found that the "positive results" found among women who take estrogen aren't scientifically valid, since the groups were selected in such a way that the women who took estrogen were healthier to begin with than the women who didn't take estrogen.

In the light of such imagined protective effects of estrogen, supplements are being recommended, either without any measurement of estrogen, or on the basis of finding a "low level" of estrogen, without taking any of the opposing or balancing factors into account. The idea of "estrogen deficiency," like that of "estrogen's protective action," is completely without scientific foundation.

Any idea of balance suggests that there could be an imbalance in either direction. The harm done by unopposed estrogenic stimulation is clear. Does an excess of progesterone occur, and if it does, is it harmful? Animal experiments, in particular, have made it clear that, at a certain level, and in the absence of interfering factors, progesterone's sedative action can reach the level of deep anesthesia. When Selye's lab technicians discovered this effect, they thought they had killed the animals, because of the animals' complete relaxation and unresponsiveness. There have been no publications of a similar effect in humans (largely because of editorial policies, rather than from a lack of experimental evidence), but if there were, the anesthetized condition would have to be characterized as being harmful only in the behavioral sense, since tissues aren't harmed. When tumors of the corpus luteum produce very large amounts of progesterone, anesthesia has never been a recognized consequence of such massive production of progesterone. Many years of animal and human study indicate that the health of the mother during pregnancy, and of the offspring, directly correspond to the amount of progesterone present. (Excess estrogen during pregnancy leads to fetal death, retardation, or subsequent health problems including breast cancer.)

Progesterone production increases tremendously during pregnancy, reaching hundreds of milligrams per day in late pregnancy, so it is hard to think of it in terms of a "hormone," as traditionally defined. Like serum albumin, I think progesterone should be thought of primarily as a physical/chemical protective substance. But, unlike albumin, its protective properties just seem

to increase with concentration, right up to the absorptive limits of the cells. (The biological protection, however, at the upper extreme, includes sedation and anesthesia, and isn't compatible with ordinary function, and so, outside of the context of pregnancy (in which sedation and anesthesia are appropriate), these can be thought of as "side effects." Since they are part of progesterone's intrinsic function, though, the idea of "side effect" has to be understood as "collateral to the intended pharmacological effect." I think the idea of "side effect" connotes a doctrine of "one substance-one effect," something the drug industry promotes.)

Progesterone's functions include antitoxic or catatoxic effects, antiswelling and antiinflammatory effects, antiglucocorticoid and antiprostaglandin effects. When it alleviates a problem, that doesn't mean that the problem was caused by a progesterone deficiency. About 30 years ago, I proposed that biological energy, differentiation, and respiratory function are integrated in such a way that certain things stabilize/increase them, or destabilize/weaken them. Radiation, anoxia, and aging cause many coherent and systematic changes in function, and some of the things that have been classified as hormones or nutrients produce similar changes. Estrogen, I suggested, was produced to take advantage of something very basic in the nature of life, to promote reparative or regenerative functions. Like radiation, hypoxia, and a variety of stressors and nutritional imbalances, estrogen causes cells to take up water, and to shift away from respiratory metabolism, going into the mitotic state.

Besides being an antiestrogen, progesterone is a neurosteroid, an antiexcitotoxin, an inhibitory modulator. But these effects in the nervous system have their parallels in the immune system, where it modulates the actions of many cells, protecting the thymus, restraining mast cell degranulation, inhibiting the shock reaction. It is an antitoxin, stabilizing cell structure and function. In the mitochondria, it preserves or restores respiratory efficiency. In.the circulatory system, it regulates heart action and vascular tone, preventing venous pooling of the blood and orthostatic hypotension, helping to keep the pulse pressure in the low range indicating efficient circulation.

Therapeutically, we can think in terms of what the organism is doing in response to its challenges, and support those processes of restoration, adaptation, inhibition, and reconstruction.

Because excitation or stress is a simple thing--it is any disturbance of the living state's quiescence--radiation damage, asphyxia, nutritional deficiencies, various poisons, carcinogens, and irritants can imitate the actions of estrogen. Or, looking at estrogen's meaning in evolution, we could say that estrogen imitates the natural menaces that life confronts, so that the processes of regeneration can be managed and integrated into the life plans of the organisms.

This means that antiestrogenic strategies are appropriate under a great variety of conditions. Whatever the challenge, a successful response will restore the organism to a new, high energy state of readiness.

Estrogen's excitatory function, acting briefly, is an integral part of the organism's preparation for reproduction, and it is involved, in an analogous way, in the response to injury, where its local release stimulates cell division. If stimulation has such generalized properties that noxious events and a natural hormone produce similar reactions, what kind of role does stimulation play elsewhere in the organism?

The interaction of energy and structure in the cell means that an energy deficit becomes excitatory. In the case of nutrition, this has been worked out in relatively great detail. Hypoglycemia, for example, causes a graded, progressive excitation, that first makes food appetizing, and then, if the excitation is continued and intensified, there is a more generalized arousal, and the image of the desired food becomes more generalized. Need and arousal mobilize various functional systems to satisfy the need. Pavlov, working on these issues, knew that it was essential to answer the question, "what stimulates the activities that we consider uniquely human?" The exploratory reflex is activated by novelty, by anything which isn't understood. The need/desire for freedom and understanding has the same basic pattern as

the other needs, and it has apparently evolved by differentiation from the basic sensitivity of the living material.

The relatively mild stimulation of novelty, when combined with meeting basic needs and preventing irrelevant, stressful stimulation, can be therapeutic. For example, in a digestive disturbance, therapeutic stimulation might be achieved by something as mild as beef broth, acting by intrinsic (unconditional) chemical processes, or by some simple alteration in the way the food is prepared, or a change in the mealtime atmosphere. The therapeutic effect of laughter, which is produced by surprise, can be seen in terms of a basic organismic process of organizing resources, creatively adapting to produce a new state of readiness.

In outline, a benign stimulation is one which can be met with adequate energy, with good humor, and with an adequate amount of progesterone and related chemical resources.

All of the information that has accumulated about estrogen in the last century leads to the view that it is the organism's means of producing a **momentary and localized imbalance,** goading cells into activity.

An important factor in the integration of this momentary imbalance into the life of the organism is the manner in which destabilizing excitation and the restoration of stability, e.g., estrogen and progesterone production, relate to each other. Estrogen stimulates the formation of progesterone, and progesterone lowers the concentration of estrogen. (Liu, et al., 1997)

Whether we consider pregnancy, or bone metabolism, or the health of the brain or the circulatory system, no situation has been identified in which the "balance of estrogen and progesterone" can be improved by the use of estrogen supplementation. But there is a tremendous amount of information showing that reproduction and the health of bones, brain, and circulatory system, and many other functions, can be improved by antiestrogenic approaches. The pharmaceutical industry is trying to exploit this information, by reclassifying their *antiestrogenic* drugs as "designer estrogens." But the body already has its proper array of antiestrogenic strategies, which can be supported in many safe and economical ways.

"Progesterone is known to selectively down-regulate nuclear estrogen receptor (Re) in the mammalian uterus, and this process is functionally related to embryo retention." "We investigated the regulation of Re by progesterone in a mammalian model (proestrous hamster uterus) and an avian model (DES-primed chick oviduct), under the same assay conditions, in an effort to compare progesterone action in viviparous and oviparous species." "Progesterone treatment reduced nuclear Re levels in both the hamster uterus and chick oviduct to about 50% of control levels." "These data indicate that progesterone rapidly and selectively down-regulates the nuclear form of Re in the chick oviduct as in the hamster uterus. Thus, the regulation of Re by progesterone appears to be similar in the mammalian uterus and the

chick oviduct, despite the basic differences in reproductive strategy between birds and mammals."

Adv Exp Med Biol 1987;230:49-78. **Progesterone-modulation of estrogen action: rapid down regulation of nuclear acceptor sites for the estrogen receptor.** Leavitt WW, Cobb AD, Takeda A. "Our previous studies demonstrated that progesterone down regulates the occupied form of nuclear estrogen receptor (Re)." ". . . we discovered that progestins stimulate the turnover of nuclear Re within 3 h of treatment, and Re synthesis is suppressed subsequently. Thus, the primary site of progestin action in down-regulating Re is the stimulation of nuclear Re turnover followed by the inhibition of Re replenishment. A major breakthrough in our understanding of how progestin controls Re turnover was made by studying nuclear acceptor sites for Re that were found to decrease markedly within 2 h of progestin treatment. These and other results indicate that progestin induces a factor called the Re regulatory factor (ReRF) which acts to block nuclear Re acceptor sites, and this in turn decreases nuclear Re retention on chromatin acceptor sites, leading to an enhanced turnover (or processing) of nuclear Re."

J Steroid Biochem 1986 Aug;25(2):219-24. **Temporal effects of progesterone domination on estrogen and oxytocin receptors in hamster uterus.** Takeda A, Leavitt WW. "The purpose of this study was to determine whether progesterone (P)-induced down regulation of estrogen receptors (Re) and oxytocin receptors (ROT) changes with the time of P exposure." "These results demonstrate that P can chronically down regulate nuclear Re and ROT. However, the control of cytosol Re varies with the time of P exposure, and cytosol Re levels become refractory to P domination by 16 days. The present observations indicate that the escape of cytosol Re from P control may be associated with the proliferation of one of more uterine cell populations such as glandular and luminal epithelial cells."

Endocrinology 1985 Mar;116(3):1079-84. **Hormonal regulation of myometrial estrogen, progesterone, and oxytocin receptors in the pregnant and pseudopregnant hamster.** Leavitt WW. "Comparison of Re and Rp levels with serum estradiol and progesterone titers revealed that receptor concentration was low when progesterone was elevated during pregnancy and pseudopregnancy. However, Re and Rp levels increased when progesterone levels dropped at the end of each condition. In comparing serum estradiol relative to progesterone at the end of pregnancy and pseudopregnancy, it was discovered that Re and Rp recovery occurred not only when the estradiol to progesterone ratio increased (pseudopregnancy) but also when the ratio did not change (pregnancy). **This suggested that serum progesterone was the primary determinant of receptor down-regulation, and this was confirmed** by comparing the receptor recovery response to estrogen and progesterone withdrawal in the decidualized hamster uterus. Total Re levels increased to the same extent after progesterone withdrawal whether or not serum estradiol was maintained. When serum estrogen was maintained at a steady state, nuclear Re (nRe) increased within 4 h of progesterone withdrawal, and estrogen-dependent protein responses (Rp and oxytocin receptor) were obtained within 8 h. Thus, progesterone-induced down-regulation of nRe and estrogen-dependent proteins is rapidly reversed upon removal of hormone. The recovery response of Re, Rp, and oxytocin receptor to progesterone withdrawal can be blocked by cycloheximide treatment at 4 h, suggesting that receptor **recovery involves protein synthesis. These results are consistent with the hypothesis that progesterone down-regulates the Re system by a selective action on nRe retention.**

Proc Natl Acad Sci U S A 1999 Mar 2;96(5):1858-62 Proteasome-dependent degradation of the human estrogen receptor. Nawaz Z, Lonard DM, Dennis AP, Smith CL, O'Malley BW Department of Cell Biology, Baylor College of Medicine. **"In eukaryotic cells, the ubiquitin-proteasome pathway is the major mechanism for the targeted degradation of proteins with short half-lives. The covalent attachment of ubiquitin to lysine residues of targeted proteins is a signal for the recognition and rapid degradation by the proteasome, a large multi-subunit protease."**. Endocrine 1997 Apr;6(2):125-131. **Estrogen replacement in ovariectomized rats results in physiologically significant levels of circulating progesterone, and co-administration of progesterone markedly reduces the circulating estrogen.** Liu JW, Dawson DD, Peters CE, Baker MA, Walker AM Division of Biomedical Sciences, University of California, Riverside.. Estrogen and progesterone replacement in ovariectomized rats in an often-used experimental system for determination of the specific effects of these hormones. In this study, two different delivery systems and two different dosage levels of estrogen, progesterone or a combination of the two have been used. Estrogen and progesterone in the circulation have been measured in response to each treatment. **It is reported that estrogen treatment (237.2 +/- 49.2 pg/mL) results in physiologically significant levels of circulating progesterone (11.1 +/- 1.3 ng/mL).** Also, co-administration of progesterone (23.7 +/- 2.0 ng/mL) with estrogen decreases the level of estrogen over that seen with estrogen alone (96.7 +/- 19.2 pg/mL with progesterone vs 237.2 +/- 49.2 pg/mL without progesterone). Thus, contrary to expectations, **estrogen replacement therapy is not specific to estrogen** and some of the antagonistic effects of progesterone are the result of a decrease in circulating estrogen, and not a specific effect on a target tissue. Whereas the mechanism of these effects has not been determined, obvious artifactitous phenomena have been excluded as being their cause. These results could have

a major impact on the interpretation of past and future experiments of this kind.

Contexts for asthma

Asthma in children involves many of the biological processes that cause disability and degeneration in the process of aging, and since the incidence of asthma in children is increasing, it has serious implications for the whole population.

Increased exposure to estrogen (including prenatal exposure), increased consumption of unsaturated vegetable oils, use of food or drug additives including guar gum, carob, carrageenan, and sulfites, and the use of adrenergic ("beta-agonist") inhalant drugs have coincided with the increased death rates from asthma. Estrogen and unsaturated fats are clearly involved in producing the symptoms of asthma.

Living at high altitude decreases asthma prevalence and mortality. Exercise increases the incidence of asthma. These facts provide insight into the biochemical events of asthma.

The inflammatory-excitatory processes of asthma are parallel to those of depression, diabetes, premenstrual syndrome, arthritis, migraine, MS, SLE, multiple organ failure, aging, and death.

Protecting cellular energy and stability can prevent or alleviate asthma. Thyroid, progesterone, and carbon dioxide are therapeutically useful, but reducing exposure to polyunsaturated oils and estrogens should be the basic approach.

Medical theories of asthma give a better insight into the nature of medicine than into the nature of the asthmatic condition.

Evasion and misdirection were woven into the culture of pharmacology by the competition to sell products. The objective result has been something approaching genocide. The U.S. government has served as the agent of the drug industry, by outlawing generic remedies whenever a corporation sought to fill that niche with its newly patented substance. This practice is so fundamental that, when inquiry is made about getting FDA approval for a substance, the response is that you must first have a patent on the substance. On its face, this indicates that the agency is in a conspiracy against the public health, to permit only proprietary remedies to be used legally.

"Medical empiricism" traditionally referred to the use of remedies that worked, without trying to build a speculative or theoretical explanation for the way they worked or for the physiological nature of disease. "Scientific medicine" decided to call that approach quackery, and to build a theory of disease that would explain how remedies worked.

As it worked out, this meant that certain kinds of remedy were "validated" by certain types of theory. Commercial and cultural interests therefore fostered and promoted the theories that they found most profitable. Impressively "scientific" words were invoked to justify procedures that otherwise would have been considered barbaric. As microscopic technique developed, "humoral" theories of disease were replaced by cellular theories, and the cellular theories came to encompass the "genetic" theories of disease.

The specific, concrete nature of the "gene" concept became part of the "allopathic" tradition of medicine, in which a specific drug was appropriate for, "indicated" for, a specific symptom or disease. The holistic ideas associated with the homeopathic tradition disappeared from organized medicine in the United States. A fragmented and compartmentalized "health science" has been the result.

In the 17th century the term *diathesis* (constitutional predisposition) was coined to "explain" disease, and the term was replaced in the 20th century by the phrase "genetic cause."

Medical writers (and medical editors) are similar to politicians and college sophomores in their habitual use of the classical logical fallacies. When students use defective reasoning, the presumption is that they are confused, but when politicians and physicians argue fallaciously, the interpretation must include other possibilities.

If a certain theoretical explanation has become unnecessary and impossible, then a growing advocacy of that theory strongly implicates ulterior motives, and suggests corrupt influences.

Although there were individuals who believed that asthma was a "psychosomatic" disease or the result of an infection, the official medical position has been that it is a diathesis, a congenital disposition, a "genetic disease" (e.g., Castro, et al., 2001; Ishikawa and Tsujimoto, 2001). A genetic theory of disease is ideal for the drug business, since incurability guarantees continuing sales. Fads in asthma theory coincide with the availability of products. The defective genes have at various times been thought to produce excessive activity in the parasympathetic nervous system, or incontinent mast cells that leak histamine, or enzyme defects that produce too much Slow-Reactive-Substance or leukotriene, or weak adrenal glands, or genetic imbalances that affect the immune system in relatively simple or in more complex ways.

Sudden increases in asthma mortality in the 1960s and 1970s in various countries corresponded to increased use of certain synthetic adrenergic drugs (instead of adrenaline), called bronchodilators, as inhalants. The concept that they were "beta-agonists" was used to rationalize their use, even after animal experiments showed that they caused serious heart damage, and other harmful effects.

When the medical model of asthma shifted its emphasis from "smooth muscle spasm" to "inflammation," a shift that in the U.S. dates from a series of publications in the 1980s (Ackerman, 1989), there was the usual sense of accomplishment, as authors and medical professors spread the word about the latest inhaled steroid products, replacing the "synthetic adrenaline" inhalants that had been increasingly used during the years that asthma mortality had been rising so rapidly. That this change of medication was thirty years tardy wasn't mentioned. (G. Rona's group began publishing warnings in the early 1960s about the heart and vascular damage caused by adrenergic drugs such as isoproteronol.) Even as new medications came into use, there wasn't much change in medical knowledge about asthma. ***And even though there is evidence that oral glucocorticoids drastically reduce death from acute asthma (Abramson, et al., 2001), and that inhaled glucocorticoids have serious systemic side effects, the drug industry created another set of mystifications, claiming that inhaling certain synthetic steroids would act selectively upon the bronchial tubes and lungs.***

As far as I can tell, the only significant event that caused the change of emphasis in the medical model of asthma from "bronchial contraction" to "bronchial inflammation" was the promotion of steroids to replace the "bronchodilators." The description of the disease seems to change according to the drug that's being marketed.

Decades ago, the public accepted the medical doctrine that asthma, and allergies in general, were caused by genetic defects. With the tremendous increase in the death rate from asthma in recent decades (coinciding with similar increases in other supposedly "genetic" diseases), many people are de-emphasizing that theory, because an impossibly high rate of mutation would have been needed to create those "new genetic defects." However, few people are looking for a radically new theory of asthma.

Asthma would be a good place to make a fresh start in understanding chronic disease, and the first step has to be to abandon the unfounded and corrupt theory of genetic causation, and to begin the construction of a functional, environmental theory of its cause. If asthma can be understood functionally, there is a good chance that it can be prevented or cured.

Elite athletes are generally considered to have "good genes," and exercise is commonly said to promote good health, so a new orientation is

needed to accommodate the fact that **"elite" athletes, winter or summer athletes, including participants in the Olympics, have a high incidence of asthma--roughly three times higher than the general population.**

It turns out that exercise induces the signs and symptoms of asthma, not only in "asthmatics," but in normal people too.

Anaerobic exercise (getting out of breath) increases the release of, or activity of, a large variety of inflammatory mediators, beginning with lactic acid and interleukin-6 released from the exercised muscle itself, and including factors released from various cells in the blood, and hormones including estrogen, prolactin and sometimes TSH.

Figures from Mexico show that, in the states with high altitude, the prevalence of asthma is about ten times lower than the states that are close to sea level. Mountain therapy has been used for a long time to treat asthma and other chronic diseases, especially in Russia. In the United States, many publications have confirmed that high altitude alleviates asthma, but it is called "antigen avoidance therapy," despite evidence that shows improvement at high altitude even in the presence of the usual antigens, such as skin mites. All of the main mediators of inflammation decrease with increasing altitude.

The incidence of asthma in girls surpasses that in boys around puberty, and it is common for asthma to be worse premenstrually. The use of oral contraceptives often makes asthma worse. During pregnancy, asthma sometimes gets worse, sometimes better. At menopause, asthma is likely to get worse, and to appear in women who didn't previously suffer from asthma. The use of estrogen at menopause increases the incidence of asthma. Progesterone, and related hormones, alleviate asthma, and this probably accounts for the variable effects of pregnancy on asthma, since pregnancy can improve the ratio of progesterone to estrogen, but often, with poor nutrition, estrogen dominance is exacerbated by pregnancy. Estrogen exposure early in life can cause asthma later. The common use of DES during pregnancy in the 1950s was one of the factors that caused the increase of asthma in children in the 1960s.

Estrogen increases most of the mediators of inflammation, which are generally inhibited by progesterone. Estrogen also shifts many processes toward excitation, and it's often hard to distinguish the mediators of inflammation from the mediators of excitation. Free polyunsaturated fatty acids, for example, which are increased under the influence of estrogen (or exercise, diabetes, nighttime, aging, histamine, parasympathetic dominance, etc.), produce both inflammation and excitation. Associated with the processes of inflammation and excitation is the tendency of estrogen and other inflammatory mediators, such as nitric oxide and serotonin, to impair mitochondrial respiration. This effect on the cells' energy production is probably responsible for many of the things that occur in asthma, such as edema and smooth muscle contraction. Acute or chronic interference with mitochondrial respiration can produce a tremendous variety of symptoms, depending on the location, and the degree of the energy deprivation. Exercise, probably acting through some of the same mediators, also impairs mitochondrial respiration.

These factors that impair respiration tend to shift mitochondrial metabolism away from the oxidation of glucose and the production of carbon dioxide, to the oxidation of fats and the production of lactic acid.

The clear distinction between inflammation and excitation (and excitotoxicity) is largely an artifact of the drug industry's influence on medical theory.

The "spasmolytic" drugs that are intended to prevent contraction of the bronchioles can cause histamine release as well as increasing cortisol production, and they increase the level of free fatty acids as well as raising the blood sugar.

Simply shifting the cells' energy production away from the oxidation of glucose can produce excitability, inflammation, increased leakiness of blood vessels, changes in mucus, discharge of histamine and serotonin, hormonal changes, etc.

The doctrine of "preventing excessive weight gain" in pregnancy that dominated obstetrics-gynecology in the U.S. in the 1950s and 1960s probably contributed to the increased prevalence of asthma in the 'sixties and 'seventies, because

protein deficiency creates an inflammatory state, and a state of estrogen dominance. (Measurement of inflammatory proteins in the blood has been proposed as a way to confirm protein deficiency.)

One of the major "acute phase proteins," C-reactive protein, is defensive against bacteria and parasites, but it is suspected to contribute to tissue degeneration. When its presence is the result of exercise, estrogen, or malnutrition, then its association with asthma is likely to be causal, rather than coincidental.

Some of the "acute phase proteins" in the blood, that are associated with inflammation, rise progressively with aging, and are induced by estrogen. One of these stress-related proteins, serum amyloid P-component, is called the "female protein" in hamsters. This type of protein is implicated in atherosclerosis, Alzheimer's disease, heart attacks, and kidney disease.

The respiratory system is so intimately related to the circulatory system and other systems that the traditional classification of diseases can be misleading. Ordinarily, asthma is distinguished from bronchitis, emphysema, "Acute Respiratory Distress Syndrome" or "shock lung," pulmonary edema, surfactant deficiency, etc., as if each problem were clearly distinguishable by its intrinsic properties. Actually, there is considerable overlap, and the diagnostic distinction can depend on the patient's history and situation, rather than on the actual pathology. Even "High Altitude Pulmonary Edema" has important similarities to "bronchial asthma."

Even though breathing might be the immediate focus of attention, there is no health problem which isn't systemic. The old medical use of cathartics for asthma, epilepsy, headaches, arthritis, cancer, etc., was often based on good observation. Before medicine became "scientific," many cases of asthma and epilepsy were successfully treated with vermifuges, but now the role of parasites in these conditions is rarely considered.

The specific location of symptoms--bronchial asthma, migraine, hemorrhoids, sneezing, etc.--brought on by an allergen, such as worms or certain foods or constipation or intestinal gas, is influenced by nervous reflexes. Reflexes are exaggerated by stresses such as hypoglycemia or alkalosis. Experimenters, for example, found that inflating a balloon in the intestine of an anesthetized animal wouldn't produce any observable reactions when the blood sugar was normal, but when the blood sugar was lowered, bronchospasms or other localized reflexive reactions would be produced.

The allergic reaction produced by any substance is intensified by hypoglycemia, and weakened by elevated blood sugar. Decreasing or increasing sodium has a similar, but weaker, effect. (G. Jasmin, 1968)

Knowing something about the situation that preceded a breathing difficulty can be useful, especially as a guide to eliminating environmental problems, but the fact that so many conditions involve the same physiological/pathological components means that a few therapies can be rationally used for many "different diseases."

For example, **caffeine, thyroid, carbon dioxide, progesterone, and several other anti-serotonin drugs (e.g., tianeptine and ketanserin)** can be therapeutic for asthma, even when the specific causes aren't known.

Buteiko's recognition of the importance of carbon dioxide (and the avoidance of hyperventilation) in the prevention of asthma is validated by the fact that high altitude normally alleviates asthma, that carbon dioxide inhalation at high altitude relieves altitude sickness (indicating that altitude sickness, like asthma, is the result of relative hyperventilation), and that acetazolamide, which increases carbon dioxide retention and is used to prevent or treat high altitude sickness, also alleviates asthma.

Practically everything which is stressful will shift metabolism away from the adequate production of carbon dioxide. The use of oxygen supplementation to treat asthma or other respiratory difficulty without also supplementing carbon dioxide is unphysiological and dangerous.

In the 19th century in the U.S., cocaine was officially recognized as a therapy for asthma, and in South America coca is the traditional remedy for altitude sickness, but there has been very little scientific investigation of the therapeutic use of cocaine. It increases progesterone production and probably has antihistamine action. Atropine,

which is very similar in chemical structure to cocaine, was a standard drug for asthma until the synthetic antihistamines and bronchodilators displaced it. Although it's known mainly as an "anticholinergic," atropine can protect against the excessive liberation of free fatty acids that interferes with the use of glucose. Camphor, amantadine, procaine and other soothing anticholinergics or antihistamines had a similar fate, as far as asthma therapy is concerned. The antihistamine Benadryl is usually helpful in asthma and other inflammatory or spasmodic conditions.

Eucalyptus oil, containing cineole or eucalyptol, is a traditional remedy for asthma, that inhibits the products of unsaturated fatty acid metabolism and the cytokines most associated with asthma symptoms.

The uncontrolled release of many inflammatory and excitatory substances can be prevented by good nutrition, emphasizing adequate protein and magnesium intake, and the use of sugars and saturated fats, rather than starches and unsaturated fats. Vitamin E protects against the inflammatory actions of the unsaturated fats. The short-chain saturated fatty acids of coconut oil have been reported to have antihistamine actions. **The selection of proteins should minimize the amino acids tryptophan (which is the precursor of serotonin) and cysteine (which, like tryptophan, suppresses thyroid function), by including gelatin and fruits.** Gelatin is 22% glycine, which protects the lungs and other organs against toxins and inflammatory agents, and many fruits are also "deficient" in tryptophan and cysteine.

The overlapping effects of estrogen, polyunsaturated fats, exercise, serotonin, histamine, lactic acid, nighttime, and hyperventilation, tend to be cumulative and self-stimulating. Degenerative changes in tissues are accelerated by all of these stress mediators.

When these factors aren't corrected, the standard officially recognized treatments for asthma--despite the acute relief they can provide--will probably increase long-range morbidity and mortality. For short-term relief, combinations of safer materials can probably be found that will give the same immediate results, while helping to correct the underlying problems.

A prospective cohort study.** Troisi RJ, Speizer FE, Willett WC, Trichopoulos D, Rosner B. We prospectively evaluated the association of hormone replacement therapy and asthma incidence in a cohort of pre- and postmenopausal women 34 to 68 yr of age. **During 582,135 person-years of follow-up between 1980 and 1990, 726 new cases of asthma were documented. Postmenopausal women who were never users of replacement hormones had a significantly lower age-adjusted risk of asthma than premenopausal women (relative risk = 0.65;** 95% confidence interval [CI] = 0.46 to 0.92). Among naturally menopausal women, the age-adjusted relative risk of asthma for ever use of postmenopausal hormones was 1.49 (95% CI = 1.10 to 2.00); for current use of hormones (conjugated estrogens with or without progesterone), 1.50 (95% CI = 0.98 to 2.30); and for past use, 1.52 (95% CI = 1.08 to 2.13), compared with never use of hormones. **Ever users of 10 or more years' duration had twice the age-adjusted risk of asthma compared with women who never used postmenopausal hormones** (95% CI = 1.39 to 2.87). Among current users of **conjugated estrogens, there was a positive dose-response demonstrated between daily dose and asthma risk (p for trend = 0.007). While confirmatory studies are warranted, these data suggest that estrogen plays a role in the pathophysiology of asthma and that long-term use and/or high doses of postmenopausal hormone therapy increase subsequent risk of asthma.**

"Daily peak flow readings and every other day hormonal studies of progesterone and estrogen both **demonstrated a positive correlation between the serum progesterone and the peak flow readings.** The addition of intramuscular progesterone (75 mg daily) to the bronchodilators eliminated the premenstrual dips in peak flow, and daily doses **of prednisolone were reduced to 5-10 mg. We suggest that a rapid fall in serum progesterone may play an important role in the pathogenesis of premenstrual asthma."**

Int Rev Immunol 1998;16(5-6):635-49. **The chronobiology of human cytokine production.** Petrovsky N, Harrison LC. "Cytokine production in human whole blood exhibits diurnal rhythmicity. Peak **production of the pro-inflammatory cytokines IFN-gamma, TNF-alpha, IL-1 and IL-12 occurs during the night and early morning at a time when plasma cortisol is lowest. The existence of a causal relationship between plasma cortisol and** production is suggested by the finding that elevation of plasma cortisol within the physiological range by the administration of cortisone acetate results in a corresponding fall in pro-inflammatory cytokine production. Cortisol may not be the only neuroendocrine hormone that entrains cytokine rhythms; other candidates include 17-hydroxy progesterone, melatonin and dihydroepiandrostene dione (DHEAS). The finding of diurnal cytokine rhythms may be relevant to **understanding why immuno-inflammatory disorders such as rheumatoid arthritis or asthma exhibit night-time or early morning exacerbations and to the optimisation of treatment for these disorders."** "Finally, diurnal rhythmicity of immune function suggests that the nature of an immune response, for example in response to vaccination, may be modified by the time of day of antigen administration and raises the possibility that immune responses could be therapeutically manipulated by co-administration of immuno-regulatory hormones such as glucocorticoids."

J Asthma 1999 Sep;36(6):511-7. **Asthma and geographical altitude: an inverse relationship in Mexico.** Vargas MH, Sienra-Monge JJ, Diaz-Mejia G, DeLeon-Gonzalez M. mhvargas@mailer.main.conacyt.mx Motivated by the great asthma-prevalence variation throughout the world, we analyzed the rate variation of medical services due to asthma in the 32 Mexican states at the Instituto Mexicano del Seguro Social (approximately 24 million **insured subjects). In 1993, a total of 406,036 services were due to asthma, and state rates ranged from 53 to 476 x 10,000 insured subjects. A direct** correlation ($p < 0.05$) was found for single-room house, ascariasis, and rubella rates, but the strongest (inverse) correlation was found for geographical altitude ($r = -0.73$, $p < 10(-5)$). Thus, in Mexico, geographical altitude affects the etiological factor(s) responsible for the development of asthma or for the triggering of asthma attacks.

Allergy Asthma Proc 1998 Sep-Oct; 19(5):263-9. **Effect of sex hormones on eosinophilic inflammation in nasal mucosa.** Hamano N, Terada N, Maesako K, Numata T, Konno A. We examined the effects of sex hormones on the functions of eosinophils. Treatment of eosinophils with beta-estradiol significantly enhanced the eosinophil adhesion to human mucosal microvascular endothelial cells (HMMEC), and eosinophils stimulated by a combination of beta-estradiol and progesterone showed significant induced degranulation. On the other hand, testosterone significantly reduced the eosinophil adhesion to HMMEC and eosinophil viability. The experiments from the series of studies might provide a partial explanation for the aggravation of asthma and some forms of rhinitis that occurs during pregnancy.

Pediatr Allergy Immunol 1997 Nov;8(4):200-4. **Is asthma an endocrine disease?** Wjst M, Dold S. The prevalence of pediatric asthma has increased in many parts of the world. This increase started more than 30 years ago and is particularly obvious in studies which document the onset of asthma in native populations when they change to a "Western" lifestyle. Besides a genetic influence, numerous environmental factors have been described for the development of asthma. **Genetic factors are unlikely to explain the sharp increase within the short time period and also allergen and pollution exposure or any specific infection does not actually seem to be the main cause for this phenomenon. Another factor, however, that fits well into the geographical and temporal background of the asthma epidemic is the mother's oral contraceptive use.** We therefore review the epidemiological association with later asthma in the children, give a summary of estrogen effects on immune function and develop a preliminary theory how oral contraception could influence later pregnancy.

"Winter athletes have an increased incidence of asthma, suggesting that repetitive hyperventilation with cold air may predispose individuals to airways disease. We used a canine model of exercise-induced hyperpnea to examine the effects of repeated hyperventilation with cool, dry air (i.e., dry air challenge [DAC]) on peripheral airway resistance (Rp), reactivity, and inflammation." ". . . other mechanisms in addition to increased smooth muscle tone may contribute to the development of repetitive hyperventilation-induced bronchial obstruction and hyperreactivity."

Exerc Immunol Rev 2001;7:66-89. **Free radicals, exercise, apoptosis, and heat shock proteins.** Fehrenbach E, Northoff H. "Evidence is accumulating that free radicals have important functions in the signal network of cells. . . ." **"Excessive exercise will also induce DNA damage in peripheral leukocytes."** "Massive intervention into the redox state by pharmaceutical doses of exogenous antioxidants should be regarded with caution due to the ambiguous role of free radicals in regulation of growth, apoptosis, and cytotoxicity by immunocompetent cells."

Med Sci Sports Exerc 2000 Aug; 32(8):1384-9. **Influence of carbohydrate on cytokine and phagocytic responses to 2 h of rowing.** Henson DA, Nieman DC, Nehlsen-Cannarella SL, Fagoaga OR, Shannon M, Bolton MR, Davis JM, Gaffney CT, Kelln WJ, Austin MD, Hjertman JM, Schilling BK. "This study examined the influence of carbohydrate (C) versus placebo (P) beverage ingestion on the phagocytic and cytokine responses to normal rowing training by 15 elite female rowers." "Concentrations of blood neutrophils and monocytes, phagocytic activity, and plasma IL-1ra were significantly lower postexercise after C versus P ingestion." **"These data indicate that carbohydrate compared with placebo ingestion attenuated the moderate rise in blood neutrophils, monocytes, phagocytosis, and plasma IL-1ra**

concentrations that followed 2-h bouts of training in elite female rowers."

J Clin Hypertens (Greenwich) 2001 May-Jun;3(3):145-52. **Gender differences in vascular compliance in young, healthy subjects assessed by pulse contour analysis.** Winer N, Sowers JR, Weber MA. "Reductions in the oscillatory or reflected component of the diastolic waveform have been observed in various clinical conditions, including hypertension, diabetes mellitus, and congestive heart failure, and may reflect endothelial dysfunction at the site of resistance vessels." **"These data indicate that female sex hormones have unexpected negative effects on small vessel compliance. They may help to explain why premenopausal women hospitalized for myocardial infarction have higher mortality rates than men of the same age."**

J Leukoc Biol 1993 Apr;53(4):420-6. **Polyunsaturated fatty acids increase neutrophil adherence and integrin receptor expression.** Bates EJ, Ferrante A, Harvey DP, Poulos A. Department of Immunology, Women's and Children's Hospital, Adelaide, Australia. Fish oils are abundant in polyunsaturated fatty acids of the n-3 series (in particular eicosapentaenoic, 20:5 and docosahexaenoic acid, 22:6). Such fatty acids are generally considered to be beneficial in the prevention of cardiac disease and to have anti-inflammatory properties. **Neutrophil adherence is an essential early event in an acute inflammatory response, and we have demonstrated that both 20:5 and 22:6 stimulate adherence in vitro. Arachidonic acid (20:4, n-6) was also stimulatory. Significant simulation of adherence was seen from 5 to 80 microM (nontoxic concentrations) 22:6, 20:5, or 20:4. At the lower fatty acid concentrations tested (< or = 40 microM) 20:5 was less active than 22:6 or 20:4 at stimulating adherence. Above 40 microM there was no difference in the ability of the three fatty acids to stimulate adherence**. At the lower fatty acid concentrations tested (< or = 10 microM) 22:6 was less active than 20:4, whereas above 10 microM they were equally active. Immunofluorescent flow cytometric analysis of neutrophil integrin (adherence) receptors showed that **the complement C3bi receptor (CD11b) was up-regulated by these fatty acids.** There was no change in CD11a or CD11c. Saturated fatty acids of the same chain length were without effect on adherence or receptor expression. The findings suggest that **these polyunsaturated fatty acids may, under certain conditions, be proinflammatory with respect to their acute effects on the interaction of neutrophils with microbes, endothelium, and other tissues.**

Both of these activities are modulated by the excitatory neurotransmitter glutamate in the hippocampus."** "Two days of estradiol treatment increased the density of NMDA agonist, but not of competitive nor noncompetitive NMDA antagonist binding sites exclusively in the CA1 region of the hippocampus. The density of noncompetitive NMDA antagonist sites, however, was decreased in the dentate gyrus by estradiol treatment." "The increase in NMDA agonist sites with ovarian hormone treatment should result in an increase in the sensitivity of the hippocampus to glutamate activation which may mediate some of the effects of estradiol on learning and epileptic seizure activity."

Epilepsia 1985 May-Jun;26(3):252-7. **Comparative effects of estradiol benzoate, the antiestrogen clomiphene citrate, and the progestin medroxyprogesterone acetate on kainic acid-induced seizures in male and female rats.** Nicoletti F, Speciale C, Sortino MA, Summa G, Caruso G, Patti F, Canonico PL. We have investigated the comparative effects of estradiol benzoate (EB), the antiestrogen clomiphene citrate (CC), and the progestin medroxyprogesterone acetate (MPA) on seizures induced by systemic injection of kainic acid (15 mg/kg i.p.) in male and female rats. **Subcutaneous administration for 10 days of EB (10 micrograms/kg) or high doses of CC (50 mg/kg) significantly potentiated kainate-induced seizures,** with this effect being more pronounced in male animals. Doses of 2.5 mg/kg of CC potentiated kainate-induced seizures in male rats but were ineffective in female rats. **Low doses of CC (0.5 mg/kg) exhibited a mild anticonvulsant effect in both sexes. Repeated administration of MPA (2.5 mg/kg) partially protected female animals against kainate-induced seizures;** in male animals, MPA induced a 30% increase in the seizure severity score, although the difference from the score of control male rats **was not significant.** These data suggest that sex steroids influence kainate-induced seizures in a sex-dependent manner and that the effects of the antiestrogen CC are dose dependent. This should be taken into account in view of a possible use of CC and MPA in hormonal therapy for seizure disorders.

Homeostasis and Aging

Thyroid mysteries and minerals: Cramps, excitotoxicity, dementia, and CO2

Blood perfusion of the brain and heart and muscles is increased by carbon dioxide, which is logical, considering that carbon dioxide ordinarily rises during metabolic activation. But the kidneys don't have this simple response to carbon dioxide, and this seems to be because of the special role of carbon dioxide in homeostasis and kidney function.

Blood flow to the kidneys is regulated by nerves and hormones. Parathyroid hormone and growth hormone cause vasodilation in the kidney, and increase its blood flow. The increased flow tends to produce a more dilute, hypotonic urine. In the kidneys, carbon dioxide's effects are much more complex than just regulating blood flow, and the kidneys maintain a remarkably high concentration of CO_2, causing some people to argue that they concentrate it from the blood.

About 88 years ago, W. F. Koch (who is known for his cancer therapy) studied the parathyroid hormone and its relation to tetany (prolonged muscle contraction) and convulsions, and was able to demonstrate that the major minerals, sodium, potassium, magnesium, and calcium are to some extent interchangeable in alleviating the tetany and convulsions produced by removal of the parathyroid gland, though magnesium was the most effective. This work was ignored by those who wanted to establish a simple relationship between "one gland, one hormone, one mechanism, one symptom or disease." A. J. Carlson's group promoted the idea that the parathyroid hormone's function was simply to increase the amount of calcium in the blood, and that it was calcium which prevented tetany. This doctrine has had far-reaching consequences.

The view which has come to dominate twentieth century biology is that organisms were assembled by a simple-minded watchmaker named Natural Selection, and that they can be understood by reducing them to their simple parts, the way we understand a watch or a motor. A polar opposite to that view would be that nature is infinite, but knowable. To understand Koch's step from tetany to cancer isn't possible within the conventions of ordinary "medical endocrinology," but Koch assumed that nature hadn't learned its methods in medical school. Koch postulated, early in the century, that electrons and free radicals were involved in the most important biological processes—respiration, movement, immunity, regeneration, etc. He was probably the first person to apply the subtleties of organic chemistry (such as the activation of chemical groups by nearby groups) to biology. (Electronic induction.) Albert Szent-Gyorgyi, a Hungarian aristocrat, recognized the complexity of nature and tried to work out a detailed scientific explanation for the ideas postulated by Koch. Szent-Gyorgyi, following Koch's interest in free radical color changes and fluorescence, understood that certain biological pigments represented special *interactions of electrons and photons with proteins,* and that muscle contraction wasn't just "a mechanical process," but probably involved all of the processes that distinguish life from death.

Books by William Frederick Koch:
Cancer and its Allied Diseases, 1926.
Natural Immunity, 1934.
The Chemistry of Natural Immunity, 1939.
The Survival Factor in Cancer and Viral Infections, 1955, 1958.

For both Koch and Szent-Gyorgyi, contraction, respiration, and cancer were life processes that required understanding the interactions of water, electrons, and proteins. Practically all other biologists ridiculed their interest in water and electrons.

(One of Szent-Gyorgyi's major projects in studying the role of respiratory energy in muscle contraction involved a strain of goat that suffers from myotonia, or chronic and generalized excessive muscle tension. I suspect that Koch's work with tetany led him in this direction.)

Szent-Gyorgyi found that progesterone and estrogen have antagonistic effects on the heart, and explained progesterone's similarity to digitalis by suggesting that it helps the cells to "build structure." The structure that he referred to in the muscle cell was the structure made up of "structured water" and proteins and regulatory substances. Carbon dioxide's concentration affects the structural energy content of the protein-water system, and this effect can nicely account for many of the mysteries of cellular heat production, including the negative heat observed in certain stages of nerve and muscle activity. Szent-Gyorgyi used a variety of electron/photon/chemical interactions to demonstrate that intracellular water has special structural properties. This line of thinking led him to a view of ionic regulation (1957) similar to Gilbert Ling's, and probably contributed to Linus Pauling's similar ideas (1960). (Szent-Gyorgyi never publicly acknowledged his respect for Koch's work, since he was obviously aware of the great dangers from the coalition of the medical-pharmaceutical establishment, the FBI, and organized crime, which drove Koch out of the United States. During the decade in which Koch operated his clinic in Detroit, it was the only large city in the U.S. in which cancer mortality declined; while cancer mortality in Los Angeles was rising by 30%, in Detroit it was declining by 20%. Immediately after the Koch episode, the same alliance conspired against Andrew Ivy and the Durovic brothers to steal the anticancer drug they called Krebiozen, but in Koch's case, they couldn't figure out just what to steal, so they tried to kill him or put him in jail. A. J. Carlson, incidentally, had a prominent role in the conspiracy against Ivy.)

Instead of receptors and effectors, locks and keys, motors and pumps, all built up arbitrarily by natural selection, the coherent view of the organism is that the **fundamental properties of matter are used and amplified and focussed by processes of tuning and balancing.** It is the "subtle reactivity" of the living system which maintains the adaptive organization of energy and structure. Part of the reactivity of the organism is the flexibly interactive metabolism, which adaptively distributes substance and energy. Ordinary metabolism, by *adjusting the affinities of the cell substance,* can account more rationally for the processes that are called "homeostatic" than the hypothetical apparatus of "pumps" and "channels," which are biology's *deus ex machina,* proposed whenever needed.

The doctrine of "one gland-one action" caused people to focus on the low blood calcium which occurs in the tetany which is brought on by removal of the parathyroid gland (which sometimes killed patients when their thyroids were removed, along with the associated parathyroids). By the 1920s, surgeons were careful about avoiding damage to the parathyroids to avoid tetany, but tetany kept occurring. They began leaving part of the thyroid gland, too, but tetany still occurred in a significant portion of patients. In fact, tetany is a risk following other operations, such as removal of the gall bladder. A new explanation for post-thyroidectomy tetany was invented, "the hungry bone syndrome," based on the idea that hyperthyroidism robs the bones of calcium, and that the bones begin stealing calcium from the rest of the body when the gland is removed. However, animal experiments show that it is only synthetic thyroxin which causes bone to lose calcium, and that the natural thyroid hormone, T_3, stimulates bone growth; also, euthyroid patients can experience tetany following removal of their thyroid.

Practically any kind of poisoning causes cells to take up calcium from the blood, so the finding of hypocalcemia in association with tetany might permit people to confuse effect with cause!

Tetanic associated ↓ Calcium

(1) Guanidine + methylguanidine + Ammoniaque = Convulsion en agissant sur les recepteurs des ac. aminé excitatrice

The doctrine of hypocalcemic tetany led to the practice of treating tetany with intravenous calcium solutions; for example, veterinarians often treat cows' "grass tetany" with large intravenous doses of calcium. The treatment works, but the tetany is now attributed to a magnesium deficiency (since magnesium supplementation works better, as Koch discovered), and excessive ammonia produced in the cow's rumen can contribute to the magnesium deficiency. The facts that have grown up in veterinary research have a strong parallel to Koch's ideas presented around 1912.

Koch found that the **convulsions produced by removal of the parathyroid glands were associated with the development of nephritis and the appearance of the toxic substances, guanidine and methylguanidine.** These compounds, and ammonia, are now known to produce convulsions by acting on the "excitatory amino acid receptors." These excitatory receptors release calcium into the cytoplasm, activating many cell processes, including the liberation of fatty acids and the breakdown of proteins. When these "receptors" are activated, the cells' energy requirement increases, and glucose is consumed more rapidly. Whenever these "receptors" are activated, magnesium will protect the cell from the "toxic" excitation. Effective antidotes to the excitotoxins have been based on their blocking of these "receptors." Amantadine is now known for its neuroprotective activity, as well as its anticholinergic and antiviral effects. In the 1950s, toxins based on the guanidine group (e.g., phenformin) were introduced to treat diabetes, because they can lower blood sugar, but they were later withdrawn because they killed the patients too quickly.

Carbon dioxide, produced by respiratory use of glucose, suppresses glycolysis, and so spares sugar. Carbon dioxide is also combined with ammonia, detoxifying it into urea. Although it hasn't been determined, I suspect that Koch's "toxic amines" are detoxified by their direct combination with carbon dioxide, which spontaneously reacts with amines to form carbamino groups. When there isn't enough carbon dioxide to combine with ammonia, the ammonia can combine with ketoglutarate, from the Krebs cycle, interfering with respiration at the same time that it produces the excitatory glutamic acid. Ammonia, in chronic poisoning, rather than producing convulsions, produces stupor and coma, and at this point, its combination with glutamic acid to produce glutamine is probably important as a defense against seizures, eliminating both ammonia and glutamic acid.

Hyperventilation, in which too much carbon dioxide is "blown off," causes tetany, and in susceptible people, can cause convulsions. Hyperventilation causes constriction of the bronchial muscles and thickening of mucus, producing symptoms of asthma. It causes contraction of blood vessels in the heart, weakening the pumping action, while blood vessels in the general circulation also constrict, raising blood pressure and reducing circulation. Hyperventilation commonly causes arrhythmia, and thickens the blood. The loss of carbon dioxide reduces brain circulation, creating complex paresthesias and stroke symptoms. "Hyperventilation" is a relative term, and refers to the amount of carbon dioxide which is lost from the blood. Heavy, rapid breathing at high altitude or in the presence of a carbon dioxide-rich atmosphere, doesn't necessarily constitute hyperventilation.

Water, proteins, oxygen, and minerals, are all crucially regulated by carbon dioxide. The enzyme, carbonic anhydrase, which is regulated by hormones (including the parathyroid hormone) and nerves, accelerates the interchange between carbon dioxide and bicarbonate, each of which has special functions. Bicarbonate is more soluble in water, but carbon dioxide is more soluble in living substance and fats. Carbonic anydrase is active in regions which regulate fluids, such as the kidney, the gut, the eye, and the vestibular apparatus of the inner ear.

Carbon dioxide limits the electrical depolarization of nerves and muscles, a phenomenon first discovered by Gilbert Ling. This prevents the over-excitation and exhaustion of brain cells and muscle cells, including the heart. The presence of carbon dioxide limits the formation of lactic acid. This explains the "lactate paradox" of high altitude exertion (lactic acid isn't produced during hypoxic exercise, since carbon dioxide is retained

by the Haldane effect, in which the low oxygen pressure fails to displace all of the carbon dioxide carried in the blood cells), and it explains why lactic acid tends to be always present in the blood in hypothyroidism, diabetes, and obesity—insufficient carbon dioxide is produced, and lactic acid is produced even without oxygen deprivation or stress. This aerobic glycolysis, the production of lactic acid in the presence of oxygen, was defined by Otto Warburg as the characteristic cancer metabolism. The "respiratory defect" in which the Pasteur effect (suppression of lactic acid formation in the presence of oxygen) fails to operate, consists largely of the failure to produce carbon dioxide in the mitochondria.

Simple hyperventilation causes muscle spasms and paresthesia (prickling of the skin), in an experiment anyone can perform in a few minutes. When a large amount of carbon dioxide is blown off, the blood's pH increases very slightly, because of systemic adjustments. The "calcium deficiency" theory of tetany would suggest that increased alkalinity of the blood decreases the "availability" of ionized calcium, and that (somehow) the "decreased availability of ionized calcium" interrupts a relaxed state of the nerves and muscles. At least, that's the explanation that I have heard many times, though I am stating it in a way that makes it sound fairly crazy. (See Stadler, et al., 1995.) But, in fact, everywhere calcium is studied, it is an activator, an excitant, a goad to activity, when it enters the cytoplasm. The evidence is that hyperventilation, which changes the serum concentration of bicarbonate, magnesium, potassium, chloride, and phosphate, does not change the serum calcium concentration, while it does *increase the intracellular calcium content.* (Fujimoto, et al., 1987; Stadler, et al., 1995.)

The combination of the calcium ion, Ca^{2+}, with the bicarbonate ion, HCO_3^-, forms a very soluble complex ion with a single positive charge. In the saliva, there is more carbon dioxide than in the mouth, and this situation is believed to explain the fact that calcium which is dissolved in the saliva tends to be deposited in an insoluble form as it loses its solublizing bicarbonate, and the insoluble form contributes to dental plaque. (Presumably, this physical principle would account for the deposition of calcium in the walls of blood vessels or in any tissue which is relatively deficient in carbon dioxide.) Similarly, when serum bicarbonate decreases, the calcium escapes from its soluble complex, and in effect the available calcium—the forms of calcium which are not bound to bicarbonate--has *increased,* exactly the opposite of what the Carlson school has argued.

Calcium, which is released into the cytoplasm by the excitotoxins, triggers the release of fatty acids, the activation of nerve and muscle, and the release of a variety of transmitter substances, in a cascade of excitatory processes, but at the same time, it tends to impair mitochondrial metabolism, and progressively tends to accumulate in mitochondria, leading to their calcification death, which is also promoted by the antirespiratory effects of the unsaturated fatty acids and the lipid peroxidation they promote. Iron and calcium both tend to accumulate with aging or stress, and both promote excitatory damage; bicarbonate contributes to keeping iron in its inactive state, and probably has a similar effect against a broad spectrum of excitatory substances. Histamine release, nitric oxide, and carbon monoxide are broadly involved in excitotoxic damage, and carbon dioxide tends to be protective against these, too.

Besides the simple excitotoxic killing of nerve cells, the processes which impair carbon dioxide production set in motion the long degenerative process that ranges from diabetic lacticacidemia to dementia. In Alzheimer's disease, brain respiratory metabolism is inhibited, creating a carbon dioxide deficiency with an excess of lactic acid and ammonia. Both Alzheimer's disease and multiple sclerosis involve depressed brain metabolism combined with an inflammatory process. In any inflamed tissue, the enzyme beta-glucuronidase is activated, and this enzyme releases estrogen within the irritated cell, activating another sequence of neurotoxic processes.

In Alzheimer's disease, two other outstanding features are the tangles of microtubular material left where cells have disintegrated, and the amyloid plaques, which often form in

extracellular spaces and around blood vessels. One of the forms of amyloid (amyloid is named for its "starchy" appearance in stained slides) is produced from the normal protein, transthyretin, which carries vitamin A and thyroid hormone, when this protein is "glycosylated," by the addition of sugar molecules. In this glycosylated form, it resembles a mutant protein, and binds to the extracellular matrix. This glycosylation can occur spontaneously and quickly, in the absence of enzymes to catalyze it, when there is too much glucose present, and when the protein's amino groups (usually lysines) are not protected by being combined with carbon dioxide (as carbamino groups). The carbamino groups form rapidly when there is an abundance of carbon dioxide, but also rapidly decompose in the absence of carbon dioxide, allowing the protein to be structurally degraded by the addition of sugar molecules.

Reactions very similar to these occur when the products of lipid peroxidation attach themselves to proteins.

Similar reactions, reflecting metabolic and energetic conditions, can alter the structure and organization of the neurotubules, leading to cell death and the formation of the characteristic neurofibrillary tangles.

W. F. Koch also found that excessive coagulation was produced in the toxic antirespiratory state. Carbon dioxide, probably by controlling the availability of calcium, is an important protection against abnormal clotting. The prevention of clotting by carbon dioxide is thought to be part of the explanation for its protective effect against oxygen deprivation. (Pak and Sverchkova, 1987.) Hyperventilation causes increased vascular permeability, leading to hemoconcentration when a large portion of the blood's water escapes into the tissues. Vascular spasm, increased viscosity of the concentrated blood, and disturbed coagulation processes undoubtedly contribute to a wide range of health problems, including stroke, heart attack, and multiple sclerosis.

Since permanent high altitude residents chronically retain a larger amount of carbon dioxide in their tissue, I have looked for data on the incidence of degenerative brain disease among high altitude populations. In Kashmir, a house-to-house study of more than 66,000 people found that nearly one percent of the population suffered from some neurological impairment, such as cerebral palsy, epilepsy, mental retardation or stroke. But no cases of Alzheimer's disease or multiple sclerosis were found. In India, the incidence of these diseases is much lower than in the U.S., but their *absence* in Kashmir is remarkable.

If excess lactic acid in the brain tissue is characteristic of Alzheimer's disease and multiple sclerosis, then the "lactate paradox" suggests that a slightly higher retention of carbon dioxide in the brain of Kashmir residents would **counteract chronic excitotoxic effects, suppressing the stress metabolism** which leads to the degenerative brain diseases. Experimentally increased carbon dioxide tends to decrease intracellular calcium, and to decrease brain excitability.

Cancer, the classical disease of extreme "aerobic glycolysis," is also negatively associated with increased altitude. Mortality from heart disease, too, decreases with increasing altitude, and the role of carbon dioxide in heart function is very clear.

The neuroprotective steroids, progesterone and pregnenolone, and magnesium and carbon dioxide all protect against excitoxicity and the related excess of intracellular calcium, while promoting normal calcification. The thyroid hormone happens to promote the production of these steroids and carbon dioxide, and the retention of magnesium. By the simple process of avoiding the antithyroid substances, especially the polyunsatured fatty acids, the degenerative processes discussed here will be minimized. Cyanide, another common component of foods (usually in the bound form as cyanogenic glycosides, in seeds, sprouts, nuts, and grains), has specific antagonisms to carbon dioxide, thyroid, and respiration.

Kosm Biol Aviakosm Med 1987 Nov-Dec;21(6):43-7. **[Role of carbon dioxide in the correction of coagulation hemostasis during hypoxia].** [Article in Russian] Pak GD, Sverchkova VS. In acute animal experiments coagulation hemostasis reactions and blood acid-base state were

investigated when dogs were breathing hypoxic (10% O2) or hypoxic-hypercapnic (10% O2, 5% CO2) gas mixtures. When given the hypoxic mixture, activation of blood coagulation was accompanied by depression of anti-coagulatory and fibrinolytic properties. These changes developed together with distinct hypoxemia, respiratory alkalosis and secondary metabolic acidosis. When given the **hypoxic-hypercapnic mixture, no hypercoagulation occurred** which can be explained by higher (than on the hypoxic mixture) paO2, lack of disorders in acid-base equilibrium and in oxygen supply. It is believed that **the ability of carbon dioxide to maintain relative normocoagulation when added to the hypoxic mixture is one of the factors that increase tolerance to hypoxia.**

JAMA 1980 Jul 4;244(1):61-2. **The effects of bicarbonate on blood coagulation.** Wong DW, Mishkin FS, Tanaka TT. The anticoagulant effects of sodium and potassium bicarbonate were investigated with use of fresh human whole blood obtained from normal healthy volunteers. Results from prothrombin and thrombin clotting time determinations demonstrated that bicarbonate can interfere with the clotting process. Clinical data obtained from patients who received intravenous administration of sodium bicarbonate supported these findings.

Nippon Geka Gakkai Zasshi 1987 Jul;88(7):864-71. **[Erythrocyte calcium and pH levels during postoperative tetany following radical operations for thyroid cancer].** Fujimoto M, Mizuno S. **To investigate the mechanism of postoperative tetany, erythrocyte calcium and pH were consecutively measured in 15 patients who underwent total removal and subsequent autotransplantation of parathyroid glands at the surgery for thyroid cancer. Of these, 8 patients presented tetany signs, but the other 7 patients had no symptoms. In the non-tetanized group, the concentration of erythrocyte calcium decreased by 33.2% and 46.0% on the 3rd and 5th postoperative day, respectively. On the other hand, it increased by 49.8% and 34.6%, respectively, in the tetanized group, showing a significantly different concentration between two groups. No significant differences were observed, however, in the serum calcium level at any time between two groups.** The erythrocyte pH as well as the plasma pH in the tetanized group was significantly higher on the 3rd postoperative day, than that in the non-tetanized group. These results suggest the possibility that the **elevated cellular calcium** content is more closely linked with postoperative tetany than the serum calcium level, and that the elevated cellular pH as well as plasma pH is another causative factor in evoking tetany.

Schweiz Rundsch Med Prax 1995, Mar 21;84(12):328-34. **[Electrolyte changes during and after voluntary hyperventilation].** Stadler G, Steurer J, Dur P, Binswanger U, Vetter W. **Paresthesia and tetanic finger cramps during hyperventilation-induced respiratory alkalosis are believed to derive from a pH-dependent decrease of ionized serum calcium. In the study reported here, ionized serum calcium, total calcium and total protein were measured during a three-minute hyperventilation period in ten volunteers. During hyperventilation finger paresthesias appeared in all probands without proof of any significant change in ionized serum calcium (1.26 +/- 0.05 mmol/l at the end of the three-minute** hyperventilation period). Total protein increased as a consequence of hyperventilation-induced transient **hemo-concentration. Paresthesias and tetanic finger cramps during the three-minute hyperventilation could not be related to changes of ionized serum calcium; however the other electrolytes, i.e. sodium, magnesium, potassium, chloride, phosphate and bicarbonate, showed, with the exception of sodium, significant changes.**

Edema, estrogen, and aging: A universal problem, and better therapies

Before talking about the harmful effects of edema, and of the things that cause edema, and of the things that can remedy the various edemas, I think it's necessary to look at a few recent events in the very long history of medicine's intervention in this problem of excessive tissue water. Otherwise, I don't think the great importance of edema, and its fundamentally "estrogenic" nature, will be clear. Aging, shock, hypertension, cancer, heart failure, and many other biological problems involve edema as a central factor, and relieving the edema is probably an essential part of solving those problems.

Carbon dioxide and estrogen are important in the regulation of water, which is a major problem in stress and aging.

Some people have defined "homeostasis" as maintaining a consistency in the things dissolved in the body's water. Physiologists have tried to explain how homeostasis is maintained, but they have had the greatest difficulty with understanding *the water itself,* and the things which allow the body to maintain the right amount of water in the various compartments of the body. ***Edema*** ("an abnormal collection of liquid") isn't a sophisticated concept, and is generally used interchangeably with "water retention" and "swelling."

Many people think of edema as an esthetic problem: They don't like the appearance of fat fingers, swollen ankles, puffy eyelids, and soggy-boggy tissues in other areas. Swollen breasts and uterus can cause pain, and often occur premenstrually along with more generalized water retention. Estrogen's role in edema is understood by many women, but therapies have generally been directed toward the water itself, with empirical diuretics, because edema's *causes* aren't explained in medical texts.

This is, to a great extent, the result of deliberate distortion by the drug industry of the issues involved. Beginning in the 1950s, the sale of new patented diuretics (replacing traditional diuretics) began in an atmosphere in which estrogen was being given to pregnant women, to prevent various complications of pregnancy (which in fact were caused by excessive estrogen). Excess estrogen as the cause of toxemia couldn't be discussed openly, and the diuretics were sold as additional tools for controlling pregnancy-associated water retention, weight gain, high blood pressure, and damage to the fetus. Pregnant women were also told to diet to limit weight gain, and to sharply limit their consumption of salt. Estrogen, diuretics, salt restriction, and dieting were demonstrably all harmful to pregnant women and their babies, but they were imposed by the pharmaceutical-medical establishment. (Besides their appalling promotion of the new diuretics "to prevent toxemia," the pharmaceutical industry presented the new chlorothiazide diuretics as the only drugs capable of correcting the "sodium problem," creating multiple unnecessary confusions.)

Shock, pneumonia, and hypertension are among the consequences of edema.

Understanding edema is essential for understanding stress, for preventing stress-induced sickness, and for resuscitation

Emphasis on diet and sodium restriction served to put the blame for pregnancy problems on the women who couldn't control their

appetites. Besides the medical obscurantism that didn't want to examine estrogen's role in toxemia of pregnancy, there was a mechanical conception of the causes of edema. Although no one could explain how a molecule could fling an atom of sodium out of a cell or across membranes such as the kidney tubules, "sodium pumps" were said to explain the different concentrations of sodium in different compartments, and water was said to passively "follow the sodium." This theory failed to explain how water could be retained while sodium was lost, or why osmotic pressure varied under certain conditions..

Physical chemists understood how water could be moved from one compartment to another, by the process of electro-osmosis, but cell physiologists still generally believe in their sodium pumps and give them responsibility for the distribution of water. Medical textbook discussions of edema have a pitiful-comical quality, because their elaborate Rube Goldberg machines* don't do what they are supposed to do, despite all their embarrassing *ad hoc* devices and convolutions.

Because of the abundance of oxygen in the world, most things are in a relatively oxidized state. Oxygen's name means "source of acid," and it creates acids because of its great affinity for electrons. Acidity is defined as a tendency to *accept electrons, or to release protons.* In water, it is common to speak only about the protons, and to think of acidity as an excess of protons, a low pH. Finely divided minerals such as clays and zeolites, and partly oxidized organic substances, have a strong tendency to absorb and bind water,because of the polar nature they have because of their oxygen content. It is extremely hard to completely dehydrate materials such as proteins and nucleic acids because of their polar, predominantly acidic, affinity for water.

*Rube Goldberg, who was educated as an engineer, described his cartoon machines as "symbols of man's capacity for exerting maximum effort to accomplish minimal results." He said "there are two ways to do things, the simple and the hard way, and a surprisingly large number of people prefer doing things the hard way."

Soluble alkaline materials, with a tendency to *release electrons or accept protons,* associate with the acidic groups, tending to produce a neutral pH. However, extremely water soluble chemicals don't have complete freedom to associate with their oppositely charged groups in materials that are insoluble in water; some enter, some are excluded. This principle can be demonstrated with drops of simple acidic organic liquids suspended in water containing ionized solutes: Their different solubility, combined with their chemical affinities, creates an equilibrium, in which the organic droplet has a negative electrical charge.

Dead cells, such as hair, behave in this way too, because this electrical and ionic behavior is normal for any acidic solid, or immiscible liquid phase. It is the failure to recognize ordinary physics and chemistry that has made Rube Goldbergian cell physiology seem plausible to so many people. Bioelectricity, and ionic selectivity, are fundamentally passive, near-equilibrium processes, that don't require any convoluted "special" apparatuses to explain them.

When oxidative metabolism enters the picture, new acids are being formed inside cells. Carbon dioxide formation is the essence of oxidative metabolism, along with the formation of metabolic water, from the interactions of carbon fuel, electrons, and oxygen. Even before carbon dioxide has covalently reacted with water, to form carbonic acid, it has a great affinity for electrons. This affinity, which predisposes it to react with water and amines, governs its non-covalent, adsorptive properties, but these are passed over by most physiologists. Carbon dioxide is chemically active in many ways, besides its contributions to bicarbonates and carbonates and carbamates and organic acids.

Both spontaneously, and enzymically, carbon dioxide combines with water. Formed inside the respiring cell, it is constantly leaving the cell as carbonic acid, bicarbonates, and carbonates. As it streams out of the cell, any positively charged group, such as a calcium ion, that it takes along will enter extracellular fluids with the carbonate or bicarbonate ion, approximately as a pair with equal positive and negative charges, but the removal of the alkaline metal ion will tend to restore the proteins' acidic nature, which had been

Acidity: accept electrons or libir protons

approximately neutralized by the passive interaction of acids and alkalis. The proteins, and the cells, will be electrically charged to a higher degree by respiration; nerve cells will show a voltage of about a tenth of a volt, while red blood cells, that don't produce energy by respiration, show an electrical potential of less than 1/400 of a volt. **This is partly a mnemonic device for visualizing the general scheme in which equilibrium conditions interact with dynamic metabolic processes.** The adsorptive effects of carbon dioxide, and a great variety of other chemical effects, modulate the cell's structure and function so that it retains far more potassium than sodium, and is able to excrete calcium while binding magnesium. But this simplified picture of carbon dioxide's effects on minerals makes it possible to understand the fact that the blood's pH is higher than the cell's, and many other mysteries, without resort to special hypothetical devices. The alkaline metals that have been mobilized from respiring cells in association with carbonic acid remain alone in the blood when carbonic acid turns into gaseous carbon dioxide and leaves the blood in the lungs. Protons, if we have to talk about them, are left in the cells, and subtracted from the blood, by the reactions of carbon dioxide, but the conventions for talking about the blood's alkalinity relative to the cells omit the background conditons: The intrinsic acidity of the cell substance, and forces exerted by the cell substance on the dissolved substances.

Myxedema, or mucous-edema, is a classical feature of hypothyroidism, but it's not always noticed, because it can occur in different tissues to different degrees. The protein that forms the mucoid jelly is partly made up of ordinary blood proteins, including albumin; transthyretin, the protein that carries thyroid hormone and vitamin A, is sometimes increased, and some connective tissue glycoproteins contribute to its bulk. Similarly to the way that mucus protects the lining of the intestine from irritants, there is probably a protective aspect to the accumulation of myxedema in stressed tissues, where it has a cushioning effect.

Starting with either hypothyroidism or hyperestrogenism, or both, since they tend to occur together, there are many pathways that lead to the excessive accumulation of water in tissues. In hypothyroidism, the adrenergic nervous system tends to overactive, and adrenalin production is sustained at a high level even when there isn't any external reason for it, since it is needed to maintain adequate blood sugar and energy, in the inefficient metabolic state of hypothyroidism.

Adrenalin mobilizes free fatty acids from tissues, including fat and muscle tissues. Estrogen itself produces elevated free fatty acids. When the free fatty acids are unsaturated, they cause edema, by making blood vessels leaky, and by making cells take up extra water; this can cause brain swelling, stiffening of the heart muscle, and thickening of the lining of blood vessels, eventually obstructing them.

Hypothyroidism suppresses respiration as a source of energy, so little carbon dioxide is produced, and lactic acid is formed even when there is no noticeable stress. This in itself resembles hyperventilation, since loss of carbon dioxide is the defining feature of hyperventilation, but the presence of abnormally high adrenergic activity, and of free fatty acids, stimulates further hyperventilation, exacerbating the loss of carbon dioxide. Decreasing the carbon dioxide impairs respiration even more, leading to increased lactic acid production, and that stimulates more adrenergic activity, and so on, in a vicious circle. Unsaturated fats also suppress respiratory production of carbon dioxide, and block the entry of glucose into cells.

Estrogen excess suppresses the liver's ability to synthesize albumin, and when this is combined with the leakage of albumin into the tissues (where it is slowly destroyed) and into the urine, the blood loses its ability to retain sodium, much of which is associated with albumin. Carbon dioxide, some of which is produced in the kidneys, helps to retain sodium, and this is probably the reason that hypothyroid people have difficulty retaining a normal amount of sodium (producing *hyponatremia*).

Both animal and human studies have shown that estrogen lowers the osmolarity of the serum and other body fluids, creating a more "diluted"

liquid. Some evidence suggests that it acts at different points to decrease the sodium (and albumin) in the blood, and to allow it to enter tissue cells, or to be lost in the intestine or urine. Although this dilutional effect of estrogen on the blood is small, it certainly increases the tendency of water to enter cells. Especially when combined with lactic acid and unsaturated fatty acids,

Since a hypotonic solution imitates the effects of estrogen, and things that cause tissue leakiness, such as cholera toxin, act like estrogen in the uterus, the edema itself produced by estrogen seems to be a central part of its normal physiological action. Histamine and serotonin and other inflammatory factors released by estrogen are known to contribute to its ability to produce edema. The excess nitric oxide produced under the influence of estrogen probably contributes to some edematous, inflammatory, and degenerative conditions. Since these effects of estrogen on tissue water are considered to be nongenomic, and independent to some extent of the normal estrogen receptors and response elements, any tissue is probably susceptible to estrogen-induced swelling, as well as to the swelling produced by unsaturated fats and carbon dioxide deficiency. Part of the toxicity of unsaturated fats could be their requirement of energy to be oxidized (S. Clejan and H. Schulz, 1986), but they reduce the efficiency of energy production in a variety of other ways.. In shock (whatever the cause), tissues become edematous, as water moves out of the blood stream. The weight of organs increases tremendously as a result of shock. In severe stress. shock, and estrogen poisoning, the production of energy is impaired by the swelling itself, though it may have been low energy production that allowed the shock-state to develop.

If estrogen can cause edema in any tissue, then antiestrogens, such as progesterone, can probably protect against stress in any tissue.

In the premenstrual syndrome, as in pregnancy, a progesterone deficiency can cause generalized edema. Tom Brewer, who founded the Society for the Protection of the Unborn through Nutrition, and S. Shanklin and J. Hodin, in *Maternal Nutrition and Child Health,* argued that salt restriction, expecially when combined with diuretics and a diet without adequate protein, caused exaggerated edema in pregnancy, producing a great risk of hypertension by reducing the blood volume needed for adequate perfusion of the kidneys, and damaged the development of the fetus, because of inadequate blood perfusion of the uterus and placenta.

After I was convinced of the manner in which salt restriction could cause edema, and knowing that women are told to restrict salt to prevent premenstrual edema, I began suggesting that women salt their food to taste, increasing their salt consumption premenstrually if they craved it. I had never known of salt restriction to prevent premenstrual edema, but I immediately began hearing that the women who ate all the salt they wanted no longer experienced premenstrual edema.

After a couple of years, I was satisfied that adequate protein and salt consistently prevented premenstrual edema. I read an article by some people who noticed that their patients who were on low sodium diets "for high blood pressure" very often developed insomnia. They knew that sodium restriction raised adrenalin levels, so they took their patients off the low sodium diet, and cured their insomnia.

Since I had become a sound sleeper as soon as I began taking thyroid, and had seen that thyroid alone would cure most people's insomnia (sometimes, as one doctor described his experience, "better than morphine") I began to understand that the adrenalin which disturbed sleep was an indicator of defective energy production, and that the things which restored sleep—thyroid, salt, sugar, protein, and progesterone, for example—were acting directly on the cells' energy production.

Since elevated adrenalin tends to raise blood pressure, I began explaining the effects of salt and thyroid to friends who were over 80. They found that they slept better, had more regular heartbeats, and didn't suffer from swollen feet when they ate a normal amount of salt. It didn't cause their blood pressure to rise.

Sodium bicarbonate and sodium chloride are known to have diuretic action; sodium

bicarbonate is often used to treat poisoning, to accelerate elimination of the toxin, for example.

Although there are complex theories about their effects, I suspect that two main processes are involved. By increasing the osmolarity of the blood, the blood volume is expanded by the entry of water from the tissues, and this increased perfusion of the kidneys would increase the formaton of urine, and, secondly, their increased concentration might simply increase the energy production of the kidneys. **The kidneys normally have a high oxygen consumption and an unusually high carbon dioxide concentration, which participates in the formation of urine. Acetazolamide, an inhibitor of the enzyme carbonic anydrase, is known to increase the body's retention of carbon dioxide,** and is sometimes used to increase the formation of urine, though its more important uses are in the prevention of edema of the lungs and brain in "mountain sickness" (a result of hyperventilation), and to reduce swelling of the eyes in glaucoma. It is also used to prevent sleep apnea, by correcting the alkalosis that causes it. The inhibition of carbonic anhydrase causes carbon dioxide retention, and this can produce acidosis. Intracellular acidosis has many important cell-protecting effects. By reducing the ionization of the cell's macromolecules, the cell's affinity for water is decreased.

Sodium bicarbonate is a more active diuretic than sodium chloride. I think this has to do with carbon dioxide's special properties, including its relative lipophilicity (preferential solubility in oils or cells), and its chemical combination with water.

Since salt restriction is the commonest way to try to correct edema, it's important to think about the physiological reasoning and evidence that support that common practice. In physiology lab classes, professors sometimes have one group of students drink a quart of ordinary water at the beginning of the class, while another group drinks a quart of isotonic saline (containing roughly a rounded teaspoonful of salt). Everyone measures their urine output over the next few hours, and by the end of the class, it turns out that those who drank the plain water produced about a quart more urine than those who drank the slightly salty water. The conclusion is obvious: For every 9 grams of salt, we retain a quart of water. That's an unfortunate experiment, though, because it creates such a clear impression of salt's immediate effect, but provides no information at all about its longer-range effects. Recently, a British physician, from Mongolia or northern China, studied the incidence of hypertension in her native region, where people consume at least 30 grams of salt per day. She found no hypertension at all, even among the oldest people. In my experiments, it has taken the body only two or three days to adjust completely to a massive change in salt consumption. Many hormones adjust quickly to retain or release sodium, according to the amount consumed, if the person is otherwise well nourished. Hypothyroid people, however, are unable to maintain a normal sodium concentration in their body fluids even when they increase their salt consumption.

Thyroid, protein, sodium, and magnesium will correct most edemas. Progesterone, acting on mitochondria to increase respiratory efficiency, and on structural proteins to change their ionic affinities, synergizes with the other natural factors to correct permeability and water regulation. One of the first people I saw use progesterone was a woman who (after being studied at the Mayo Clinic and many other places) believed she had Bright's disease, and habitually produced an extremely small quantity of urine. A few hours after taking just a few milligrams of progesterone, she telephoned to report that she "had to stop at every gas station on the way home," because she was forming urine at such a great rate. Increased perfusion of the kidneys is one of progesterone's normal functions, that accounts for its ability to prevent or cure "toxemia" of pregnancy. Besides its ability to increase blood perfusion of the kidneys (and other organs), progesterone has an important role in mineral regulation, since it acts as a "weak aldosterone," protecting against both a deficiency and an excess of that adrenal hormone. (The kallikrein enzymes which produce kinins and related hormones are probably involved in the effects of progesterone, estrogen, fatty acids, etc., on the permeability of blood vessels, blood

pressure, swelling, etc., but researchers have surprisingly little interest in that system..)

Brain edema causes seizures, lung edema causes "respiratory distress syndrome," and is a factor in pulmonary hypertension. In the heart and blood vessels, it increases rigidity and decreases the efficiency of blood circulatoin. Degenerative nerve and muscle diseases often begin with edema; degenerative spinal disks, and lens cataracts, are produced by an excess of water.

Although estrogen increases during acute sickness in both men and women, women have a higher incidence of estrogen-related diseases than men do. In spite of a large number of degenerative diseases caused by estrogen, women live significantly longer than men do, and both animal and human studies have shown that it is probably progesterone which gives women this advantage.

It is this female longevity that has allowed the drug companies to suggest that estrogen can prevent degenerative diseases. Estrogen's known promotion of clotting diseases, edema, diabetes, liver disease and blood pressure abnormalities, are ignored while cholesterol is emphasized as a "risk factor" that is favorably influenced by estrogen. Estrogen's elevation of free fatty acids, and the edema produced by these, are ignored as if they had no significance in the degenerative diseases.

I have already written about estrogen's contributions to brain aging and blood clotting diseases, but I plan to write soon about progesterone and thyroid as the important "heart protective" hormones.

Prostate Cancer

It was noticed several decades ago that estrogen causes the prostate gland to enlarge in experimental animals, but by then an oversimplified view of the sex hormones was already well established, that led people to say that "estrogen causes the female organs to grow, and testosterone causes the male organs to grow." Logically extending this mistaken idea led many of the same people to suppose that the "hormones of one sex would inhibit the growth of the reproductive organs of the other sex."

When a friend of mine was told he had prostate cancer, though he had had no symptoms, and should receive large doses of estrogen, I reviewed the literature, to see whether his doctor might have seen something I had neglected. Since that time, I have found it necessary to use quotation marks around the phrases "medical research" and "medical science," because there is a certain kind of "research" performed within the medical profession which is peculiar to that profession.

When I read through the studies cited by the current articles as the basis for using estrogen to treat prostate cancer, I saw that the decisive "research" had consisted of mailing a questionnaire to physicians asking them if they thought it was reasonable to administer estrogen to these patients on the basis of its opposition to testosterone, which was considered to be responsible for the growth of the prostate gland. Many physicians answered the questionnaire affirmatively.

If the questioner's purpose was to determine his legal status in using a treatment, his research method was appropriate, to see whether the treatment seemed reasonable to others in the profession. Legally, a physician is safe if he can count on others to testify that his practice is standard. Unfortunately, for generations his study of the opinions of his peers became the "evidence" of the value of the estrogen treatment. Phrases such as "it is indicated," "treatment of choice," and "standard practice" are used in medicine, as part of the pseudo-scientific mystique of the profession. Physicans who attempt to base their practice on methods that have a sound scientific basis are likely to find that they are violating the norms of their profession.

More than 25 years ago, when I started pointing out that deliberate misrepresentation had been involved in the continued designation of estrogen as "the female hormone," used as a basis for "hormone replacement therapies," I saw that it was hard for people to sustain a critical attitude toward language. Language is prior to judgment, law, science, reason. Those who define the terms set the rules.

> **"...simultaneous treatment of intact...rats with testosterone and estradiol-17beta for 16 weeks consistenly induced a putative precancerous lesion, termed dysplasia, in the dorsolateral prostate of all animals. Since treatment of rats with androgen alone did not elicit the same response, we concluded that estrogen played a critical role in the genesis of this proliferative lesion."** ***Shuk-mei Ho and M. Yu, in "Selective increase in type II estrogen-binding sites in the dysplastic dorsolateral prostates of Noble rats," Cancer Research 53, 528-532, 1993.***

By the mid-1980s, some studies had shown that estrogen treatment didn't prolong the survival of prostate cancer patients at all, but it was argued that the patients who received estrogen were happier than those who didn't.

Apparently, many physicians who were experts in conventional cancer treatment hadn't been impressed by the happiness of their patients

who were receiving estrogen, because a survey at a conference of physicians found that many of them would choose to have no treatment if they learned they had prostate cancer. And more recently, there have been recommendations that older patients shouldn't be treated aggressively, because their cancers are usually so slow growing that they are likely to die of something else related to old age.

In spite of the articles I showed my friend, and my warning that estrogen can cause strokes and heart attacks, he decided to take the estrogen treatment. Within a few days he began suffering from asthma and disturbed sleep. Then he had a series of strokes and died.

Since it was known that estrogen treatment was dangerous for men, and that it increases blood clotting and vascular spasms, there had to be some overriding belief that led to its general use in treating prostate cancer. That belief seems to be that "estrogen, the female hormone, opposes testosterone, the male hormone, which is responsible for the growth--and therefore for the cancerization--of the prostate gland." Everything is wrong with that sentence, but you can find every part of the belief present and functioning in the medical literature. Just to give some context to the association of growth and cancerization, I should mention that Otto Warburg observed that all of the carcinogenic factors he studied caused *tissue atrophy before cancer* appeared. Another important contextual point is that every hormone does *many* things, and every endocrine gland produces multiple hormones.

Since the time of Brown-Sequard and Eugen Steinach, it has been accepted that declining testicular function is a common feature of aging, and testosterone was probably the first hormone that was clearly found to decrease consistently with aging. (Vermeulen, et al., 1972, 1979.)

It has seemed odd to many people that enlargement of the prostate should occur mainly in older men, if testosterone is the hormone that causes its growth, and estrogen is antagonistic to its growth. The nature of the growth of the old man's prostate is very different from its natural growth in youth.

It was also recognized decades ago that estrogen rises in men during old age (Pirke and Doerr, 1975), as it rises in stress, disease, malnutrition, and hypothyroidism (which are also associated with old age). Estrogen is produced in fat (Siiteri, and MacDonald, 1973, Vermeulen, 1976) which tends to increase with age, when thyroid and progesterone are deficient. The conversion of testosterone to estrogen occurs in the testicle itself, but this conversion is also inhibited by the favorable hormonal environment of youth. The active thyroid hormone, T_3, declines with aging, and this necessarily lowers production of pregnenolone and progesterone. Increasingly, in both sexes, it appears that DHEA may rise during stress as a result of a deficiency of thyroid, progesterone, and pregnenolone.

In 1786, John Hunter reported that castration causes a decrease in the size of the prostate gland, and by the end of the 19th century castration was being advocated for treating enlargement of the prostate. In aging men, the prostate gland (both central and peripheral zones) atrophies, and it is within the atrophic gland that cancer cells can be found. Nodular, noncancerous enlargement may occur, with or without cancer. In 1935, an autopsy study showed carcinoma in the prostates of 30% of men by the age of 50. Proliferation of ductal and epithelial tissue is closely associated with prostate cancer, a situation similar to that of the cancerous or precancerous breast. (Simpson, et al., 1982; Wellings, et al., 1975; Jensen, et al., 1976.) The high probability of "epitheliosis" in association with cancer was seen in women in their early 40s, and in women over 60. (Simpson, et al.) (Epitheliosis just refers to an exaggerated proliferation of epithelial cells, the cells covering all surfaces, including the lining of glands, and things as simple as irritation and vitamin A deficiency can cause these cells to proliferate.) In the breast, the proliferative epitheliosis is clearly caused by estrogenic stimulation. The antagonism between estrogen and vitamin A in controlling epithelial proliferation (and possibly other cell types: Boettger-Tong and Stancel, 1995) is clear wherever it has been tested; vitamin A restrains epithelial proliferation. (Wherever estrogen is a factor in the development of

En vieillissant le ratio estro/antiestro ↑

abnormal tissue, vitamin A supplementation would seem beneficial.)

In aging women and men, as the breasts and prostate atrophy, their estrogen/antiestrogen ratio increases.

In men with prostate cancer, the fluid secreted by the prostate contains significantly more estradiol than the fluid from men without cancer (Rose, et al., 1984). This is analogous to observations made in women with breast cancer.

The pituitary hormones have diverse functons, including effects on epithelial tissues, other than their "classical" functions. Growth hormone, ACTH (Lostroh and Li, 1957), and ACTH with prolactin (Tullner, 1963) stimulate prostate growth. Prolactin--which is increased by estrogen--stimulates growth of the rat's lateral prostate (Holland and Lee, 1980), and stimulates the growth of human prostate epithelial cells *in vitro* (Syms, et al., 1985). LH (luteinizing hormone) increases when progesterone or testosterone is deficient, and growth hormone and prolactin (which are closely associated in evolution) both increase under a variety of stressful situations, and with estrogenic stimulation. **Prostate cancer patients who had higher levels of LH and *lower testosterone* died most quickly. (Harper, et al., 1984.) Also, a *high ratio of testosterone to estradiol or of testosterone to prolactin* corresponded to better survival (Rannikko, et al., 1981.) Considered separately, patients with *higher testosterone levels had a better prognosis* than those with lower levels, and patients with lower growth hormone levels did better than those with higher growth hormone levels. (Wilson, et al., 1985.)** Has anyone ever tried testosterone therapy for prostate cancer? Or, more practically, a generalized antiestrogenic therapy, using thyroid, progesterone, and pregnenolone? Other drugs (naloxone, bromocriptine, gonadotropin-releasing hormone agonists, and anti-growth hormone druges, e.g.) are available to regulate the pituitary hormones, and might be useful therapeutically or preventively. (See Blaakaer, et al., 1995.) Biskind and Biskind's work (1944) with ovarian tumors might be relevant to both testicular and prostate cancer.

Abnormal patterns of pituitary hormones reflect stress and hormonal imbalance, but they are also directly involved in widespread changes in tissue content of glycoproteins. The prostate is specialized to secrete large amounts of mucin. The endocrine physiology of prostate mucin secretion is poorly understood, but it is likely that there are interactions between growth-regulatory and secretion-regulatory systems.

In recent years, prostate cancer has been one of the fastest increasing kinds of cancer, and it isn't apparent that increased treatment has had an effect in lowering the death rate. The postwar baby-boom (following the baby-bust of the great depression) created an abnormal age-structure of the population, that has been used to argue that the war against cancer is being won. Increasing environmental estrogens are known to cause many reproductive abnormalities, and their contribution to prostate cancer would get more attention if estrogen's role in prostate disease were better known. Environmental estrogens are clearly responsible for genital deformities and sterility in many species of wild animals, but when the causal link is made between estrogens and human abnormalities, the estrogen industry sends its shills in to create controversy and confusion. Even the effects of estrogens in sewage, known for decades, are treated as State Secrets: "There had been reports of hermaphroditic fishes in one or two rivers, and government investigators had been studying them since the late 1970s. **But no one had been aware of the work because it was classified."** (Lutz, 1996.)

Testicular cancer is easy to diagnose, and its incidence has clearly increased (100% in white men, 200% in black men) since 1950. Undescended testicles, urethral abnormalities, etc., similar to those seen in DES sons and in wild animals, have also increased. So the tremendous increase in the death rate from prostate cancer during the same time has a meaningful context.

Although the animal studies showed that estrogen treatment promotes enlargement of the prostate, it was possible to suppose that the human prostate's growth might be stimulated only by testosterone, until tests were done *in vitro* to

GH + Prolactine + ACTH stimule la croissance de la Prostate
↑ cmt ↑ par stress et estro. Si ↑ testo & estro ou testo & Rapport test Bon

Testo ne stimule pas la ÷ cellulaire mais Insu et Prola oui'

determine the effects of hormones on cell division.

In human prostate slices, several hormones (including insulin, and probably prolactin) stimulated cell division; **testosterone did not,** under these experimental conditions. (McKeehan, et al., 1984.) Contrary to the stereotyped ideas, there are suggestions that supplementary androgens could control prostate cancer (Umekita, et al., 1996), and that antagonists to prolactin and estrogen might be appropriately used in hormonal therapy (for example, Wennbo, et al., 1997; Lane, et al., 1997).

By the age of 50, men often show an excess of both prolactin and estrogen, and a deficiency of thyroid and testosterone. This is the age at which enlargement of the prostate often becomes noticeable.

Estrogen's role in prostate growth and cancerization is clear: "...simultaneous treatment of intact...rats with testosterone and estradiol-17beta for 16 weeks consistenly induced a putative precancerous lesion, termed dysplasia, in the dorsolateral prostate of all animals. Since treatment of rats with androgen alone did not elicit the same response, we concluded that estrogen played a critical role in the genesis of this proliferative lesion." (Ho and Yu.)

Progesterone and pregnenolone also decline in aging men. Several studies using synthetic progestins have shown that they effectively shrink the hypertrophic prostate, and the saw palmetto remedy for prostate enlargement has been reported to contain pregnenolone, or something similar to it. These materials might be expected to reduce conversion of testosterone or other androgens to estrogen.

The prostaglandins were discovered in prostatic fluid, where they occur in significant concentrations. They are so deeply involved with the development of cancers of all sorts that aspirin and other prostaglandin inhibitors should be considered as a basic part of cancer therapy. The prostaglandins have local and systemic effects that promote cancer growth. ("The prostaglandins and related eicosanoids synthesized from polyunsaturated fatty acid precursors have been implicated as modulators of **tumor metastasis, host immunoregulation, tumor promotion, and cell proliferation."** Hubbard, et al., 1988.)

Estrogens cause elevation of free fatty acids, and there are many interactions between the unsaturated fatty acids and estrogen, including their metabolism to prostaglandins, and their peroxidation. Estrogen's roles as free-radical promoter, DNA toxin, carcinogen, tumor promotor, modifier of tissue growth factors, anti-thymic hormone, etc., as well as its local effects on the prostate gland, have to be kept in mind. Most of the interest in studying estrogen's contributions to prostate cancer relates to the existence of estrogen receptors in various parts of the prostate. While that is interesting, it tends to distract attention from the fact that many of estrogen's most important actions don't involve the "receptors." A **direct excitatory** action on prostate cells, and **indirect** actions by way of the pituitary, pancreas, thyroid, adrenal, fatty acids, prostaglandins, histamine and circulation are probably essential parts of the cancerization process.

The unsaturated fatty acids, but not the saturated fatty acids, free estrogen from the serum proteins that bind it, and increase its availability and activity in tissue cells.

Thyroid supplementation, adequate animal protein, trace minerals, and vitamin A are the first things to consider in the prevention of prostate hypertrophy and cancer. Nutritional and endocrine support can be combined with rational anticancer treatments, since there is really no sharp line between different approaches that are aimed at achieving endocrine and immunological balance, without harming anything.

Avoiding tissue atrophy is very closely related to promoting healthy regeneration. These processes require efficient energy production, and an appropriate balance between stimulation and resources. Growth hormone is sometimes recommend to correct tissue atrophy, but the evidence seems reasonably clear that it is a factor in the promotion of tumefaction of the prostate. The only study I have seen suggesting that it might be beneficial in prostatic cancer was a 14 day experiment done in female rats. Numerous publications suggest that blocking growth hormone is

AGING = ↓ THY, ↓ PREG, ↑ estro ; ↑ testo en excès dans Testi, ↑ stress gen ↑
GH, Prola, insuline, ACTH et cort ↑ ÷ cellulaire ON supp de THY, Preg, A, Protéine cost bon

beneficial in treating prostate cancer; in future newsletters I will be discussing the evidence that growth hormone, like estrogen, cortisol, and unsaturated fats, tends to promote degenerative changes of aging.

"We, and others, have previously described the histological changes that occur in the prostate gland of intact Noble (NBL) rats following prolonged hormonal treatment. Dysplasia, a pre-neoplastic lesion, develops specifically in the dorsolateral prostates (DLPs) of NBL rats treated for 16 weeks with a combined regimen of testosterone (T) and estradiol-17beta (E2) (T + E2-treated rats). **Concurrent with DLP dysplasia induction, the dual hormone regimen also elicits hyperprolactinemia, in addition to an elevation of nuclear type II estrogen binding sites (type II EBS), no alteration in estrogen receptors (ER), and marked epithelial cell proliferation in the dysplastic foci.** The aim of this study was to investigate whether the dual hormone action is mediated via E2-induced hyperprolactinemia. Bromocriptine (Br), at a dose of 4 mg/kg body wt per day, was used to suppress pituitary prolactin (PRL) release. Serum PRL levels were lowered from values of 341 +/- 50 ng/ml in T + E2-treated rats to 32 +/- 10 ng/ml in Br co-treated animals. The latter values were comparable to those in untreated control rats. In addition, Br co-treatment effectively inhibited the evolution of dysplasia (six out of eight rats) **and the often associated inflammation** (five out of eight rats) in most animals. In contrast, Br co-treatment did not suppress the T + E2-induced type II EBS elevation nor alter ER levels in the DLPs of these rats, when compared with T + E2-treated rats. These data extend the many previous studies that have detailed marked influences of **PRL on rat prostatic functions. However, the current study is the first to implicate PRL in prostatic dysplasia induction in vivo."**

Wennbo H, Kindblom J, Isaksson OG, Tornell J., Endocrinology 1997 Oct;138(10):4410-4415. "Transgenic mice overexpressing the prolactin gene develop dramatic enlargement of the prostate gland," "An altered endocrine status of elderly men has been hypothesized to be important for development of prostate hyperplasia. The present study addresses the question whether increased PRL expression is of importance for development of prostate hyperplasia in mice. Three lines of PRL transgenic mice were generated having serum levels of PRL of approximately 15 ng/ml, 100 ng/ml, and 250 ng/ml, respectively. These mice developed dramatic enlargement of the prostate gland, approximately 20 times the normal prostate weight and they had a 4- to 5-fold increased DNA content. Histologically, the prostate glands in the transgenic mice were distended from secretion, and the amount of interstitial tissue was increased. The levels oftestosterone and IGF-I were increased in the PRL transgenic animals. In mice overexpressing the bovine GH gene, displaying elevated IGF-I levels, the prostate gland was slightly larger compared with normal mice, indicating that the effect of PRL was not primarily mediated through elevated plasma IGF-I levels. **"The present study suggests that PRL is an important factor in the development of prostate hyperplasia** acting directly on the prostate gland or via increased plasma levels of testosterone."

Hayflickers, Dolly & dandruff: The "telomeric clock" is not a valid theory of aging.

The roles of nutrition, estrogen, and progesterone in stress-related energy problems: A meaningful pattern for all organisms.

I. Introduction

Besides the commercially promoted idea that melatonin has something to do with a "biological clock," there are two main doctrines among biologists about the nature of the clock that they suppose exists. One group argues that a group of brain cells called the suprachiasmatic nucleus has a regular rate of firing that is "determined by genes" and that controls biological rhythms. Unfortunately for that theory, the firing rate of those cells turns out to be variable under different conditions of metabolism and temperature (Ruby and Heller, 1996).

"Estrogen's identity as a shock-hormone gives an insight into the context-dependent aging of cells and carcinogenesis. The pro-respiratory progesterone is involved as estrogen's antagonist at the deepest molecular levels."

Another general kind of clock is proposed to be "determined by the genes," or genetically "programmed," and in this case the clock is supposed to determine how long an animal can live.

Neither of these groups has even tried to dispose of the facts that have accumulated over several decades suggesting that there is no independent biological clock at all, but rather an ability of cells and organisms to perceive rhythmic environmental conditions. Frank A. Brown, Jr. (Univ. of Indiana) and Alexandre Rothen (Rockefeller Univ.) devised many experiments that clearly demonstrated that biochemical, metabolic and physiological rhythms are responsive to cues other than light and darkness. The geomagnetic field is one type of cue that has demonstrable biological effects.

The doctrine of a genetic clock causing aging denies the role of environmental factors in the aging process. Cigarette companies argued that "we *don't know* the cause of cancer, so go ahead and smoke." The genetic clock people claim to *know* the cause of aging, and that it is not environmental factors.

"The stem cell is defined as that cell in a tissue which, under normal circumstances, maintainsits own population, undiminished in function and size, and furnishes daughters to provide new functional cells of that tissue.The daughters may, or may not, have to undergo further differentiation and/or maturation in order to achieve their functional stage. The fundamental characteristic of a stem cell, therefore, is self-renewal. Evidence is presented which implicates the microenvironment as a major component of the stem cell system, without which stem cells cannot be maintained. Furthermore, it is suggested that stem cell properties do not reside in one specific cell type in the population but, when necessary, cells other than those normally playing the stem cell role, can have stem cell function imposed upon them by the appropriate microenvironment. The stem cell "niche" hypothesis is presented to explain the dependence of stem cells upon their microenvironment. The postulate is offered that there are no cells which are intrinsically stem cells but that a range of cells in a tissue possess stem cell potential to a greater or lesser extent." "The stem cell system," R. Schofield, Biomed Pharmacother, 1983, 37:8, 375-80.

can live much longer than the animal they came from, and that the age of the donor doesn't determine the survival of the transplant.

Studies of the rate of cell division in the lining of the intestine and of the bone marrow cells that continuously produce red blood cells throughout the life-span also have shown gross violations of the "Hayflick limit." Dandruff, the result of the steady division of cells in the epidermis, and the growth of nails and hair, are easily visible demonstrations that Hayflick's observations were just the result of the special conditions he created in his cell culture bottles.

The gradual accumulation of support for the principles Carrel outlined includes evidence that cell-to-cell interactions (R. Auerbach, 1972), adequacy of glucose supply, oxygen and carbon dioxide, appropriate pH, osmolarity, hormones, extracellular matrix (Gospodarowicz), hormones, and many regulatory substances including proteins and fats, **can fundamentally change the ability of cells to divide in culture vessels.**

For example, Gospodarowicz, et al. (1983) found that growing cells on "extracellular matrix," and with some natural substances from serum, rather than on plastic, made the difference between an *in vitro* longevity of 15 or 24 divisions, and "at least 88" cell divisions.

If the "intrinsic cell aging" people want to talk in terms of "programming," then we would have to say that cells are constantly open to "reprogramming," which is to say that they are perceptive and responsive to their environment.

Hayflick's method began with tissue that could be kept, either at room temperature or at 5 degrees, "for at least 5 days" (and "up to 3 weeks") "without apparent loss of viability." Although lactic acid production is a sign of stress, it seems that Hayflick took it as an indication of life: "Once the cultures have become confluent cell sheets, the cells are very active metabolically, as shown by the fact that the GM [growth medium] becomes acid faster than in cultures of heteroploid cell lines inoculated with the same number of cells." "Although mitotic activity eventually ceases in the culture, acid production continues; and as dictated by drops in the pH, cultures can be fed for a few months until all acid production ceases and the culture is observed to have completely degenerated." Among the ridiculously antiphysiological conditions used in Haflick's experiments was the addition of high concentrations of penicillin and streptomycin, or aureomycin, to the growth medium. (See Pershadang, et al., 1982.) He refers to Carrel's techniques as "primitive," and says "In any event, Carrel's experiment has never been confirmed." (Carrel's experiment continued for 35 years, so it will be a while before anyone repeats it.) **Carrel's "primitive" method involved frequent addition of chick embryo extract** rather than Hayflick's commercial solutions of salts, buffers, and antibiotics, with the addition of very small amounts of calf or horse serum. Using fluids from the same species, from an embryo rather than from an adult, and avoiding harmful additives, might be more properly called a sophisticated technique, rather than primitive incompetence. (Smith, et al., 1985, showed that DNA "repair capacity was always found to be greatest in medium supplemented with autologous plasma.")

The essence of the telomeric clock doctrine is that the telomere shortens with aging, making cell division impossible, and causing the organism to suffer the symptoms of aging, while the "immortal germ cells and cancer cells" have active telomerase that allows them to maintain long telomeres. Besides the "inappropriate" telomere length that has been seen in some individuals of different ages, there are so many exceptions to the rule that it is inaccurate to speak of a rule.

Mice, with a very short life-span, have active telomerase in their body tissues, while people normally don't. Telomerase isn't needed to form or maintain telomeres. Some cancers have long telomeres, some don't. Telomere length varies between organs in the same animal, and even between chromosomes in the same cell.

To say that the theory of the telomeric-mitotic clock is complete junk is not to question the importance of the telomere itself--like any part of the cell, it is complex, important, and interesting.

La cell n'est pas limitée et dépend de l'on glucose, Dioxide de C., pH, hormone, macro, micro et peu se reprogrammer par rapport à son environnement

IV. DNA, stress, and estrogen

If Hayflick and Carrel have anything in common, it is the observation that aging is closely associated with the slowing of cell division.

Carrel's observation that the rate of healing is slower in old individuals has been repeated in different systems, for example (Lambert, et al., 1979) **showing that DNA repair synthesis is retarded in cells from old people. Estrogen also slows DNA repair** (O'Brien, 1993), as well as causing increased DNA breakage.

Estrogen's identity as a shock-hormone gives an insight into the context-dependent aging of cells and carcinogenesis. The pro-respiratory progesterone is involved as estrogen's antagonist at the deepest molecular levels.

Fifty years ago, estrogen was shown to imitate all of the physiological features of the shock phase of the stress reaction, and later it was found that histamine and estrogen (and now, nitric oxide) have parallel shock-promoting actions.

More recently, cells (all kinds of cell, including bacteria) have been found to have a system of proteins, called heat shock proteins, that are produced in response to any stress or shock, and estrogen turns out to have a very close association with these stress-induced proteins. Estrogen induces the heat shock proteins, and the heat shock proteins activate or **stabilize the estrogen receptor, so that injury in general facilitates the action of estrogen on the cell.** Progesterone and its receptor have an opposite and antagonistic effect on the heat shock proteins.

In 1970, my proposal that the estrogenic state and the senescent state were very closely related seemed strange to people who had heard estrogen treatment promoted as the way to prolong youth and to stay "forever feminine," but a few years after I had finished my dissertation, Terry Parkening, who had worked in Proferssor Soderwall's lab at the same time I had, began publishing observations of elevated estrogen levels in a variety of aging animals. Estrogen is now known to increase with athletic stress, trauma, sickness, endotoxin poisoning, etc., and to be an essential factor in prostate cancer, as well as in essentially all other cancers, so it doesn't seem to be such a big step to go from "stress hormone" to "age hormone." Estrogen is beginning to lose its false identity as the "female hormone," which was always just a promotional concept of the pharmaceutical industry. Hundreds of false claims have been made about estrogen's "youth promoting" effects, but they always turn out to be the opposite of what is claimed. For example, "estrogen increases the collagen content of skin," but in fact collagen accumulation is characteristic of aging, radiation injury, and many other types of damage. "Estrogen makes the skin plumper," but it is by causing water retention; bloating might stretch wrinkly skin until it is smooth, or even tight, but a swollen old face is, if anything, biologically older than a lean and creased face. (I have discussed many other such advertising ploys in my books, e.g., *From PMS to Menopause: Hormones in Context.*)

The types of adaptation to stress that are known to occur both *in vitro* and in normal aging of the animal, include the various defensive systems such as the heat shock proteins, which are induced by stresses that interfere with the cell's energy supply.

During the last 35 years there have been many demonstrations that cells in culture do not get an optimal amount of oxygen. (Wolffe, et al., 1984, for example.) Kondo et al. (1997) have recently shown that cells grown at the interface where the culture medium meets the air are more like normal cells: They "possess highly differentiated functions and structures compared with the cells cultured under immersion." Previously, as Warburg pointed out, it was found that the cells that grow in a sheet on the bottom of the vessel were much more oxygen-deprived than the cells which are immersed, but suspended, and receive oxygen and nutrients from all sides.

Suffocation and x-ray injury produce an estrogen-like response in animals. The oxygen deprivation in tissue culture, which Warburg showed created the characteristic cancer metabolism, produces the pro-estrogenic heat shock proteins, as well as other stress substances. The antagonism of progesterone to the actions of this heat stress system gives us

Stress ↑ Heme oxygenase (Protéine) level ↑ Carbon monoxide et leur ↑ métabo du cancer
métabo du cancer = glycolyse aérobie avec acide-Lactique : Pas normal car O2 est là

further insight into how to redirect cells away from the stress pathway.

During oxidative stress, a variety of stress proteins are produced, besides the heat shock system. Heme oxygenase, which produces carbon monoxide, is one of these stress proteins, and I have previously discussed how this stress-induced production of carbon monoxide could stabilize the cells' dedifferentiated tumor-producing state, since carbon monoxide produces what Warburg has characterized as the "cancer metabolism," aerobic glycolysis, in which cells produce lactic acid even in the presence of oxygen. In Hayflick's original article (Hayflick and Moorhead, 1961), the production of lactic acid by the cells doesn't seem to be of interest to the authors. I have also introduced the idea that the stress-proteins could have far reaching effects through an effect on the structure of water.

But apart from those points, it is now well established that the heat shock proteins stabilize and reinforce the effects of estrogen. Estrogen tends to shift cells away from differentiated functioning and toward simple cell division, a sort of dedifferentiation. This cell division is important for reproduction, and it is also part of a basic process of tissue regeneration. **During stress or injury, as well as in normal growth, cells have to make the basic decision of whether to grow or to die in the non-inflammatory process called apoptosis, or to differentiate and contribute to the functional systems of the organism.** The heat shock/estrogen system protects cells against "altruistic cell death," but ordinarily the organism rescues the cells from that dedifferentiated state by providing energy, oxygen, and signals to restore them to an appropriate functional state.

The stress pathway at first stimulates cell division, directing cells to differentiate down a pathway that is useful in tissue repair, but this stress-response is not useful in the culture dish, and the absence of the rest of the organism means that nothing will come from their growth decision, other than persisting under the damaging, stressful conditions.

In Hayflick's cell culture, the cells were clearly under sufficient stress to activate their estrogenic cell division process, but in the absence of either adequate energy or appropriate signals, they were on a dead-end path. The specific substances in the culture medium could be investigated if we needed to know the detailed cellular physiology of that dead-end path, but giving serious scientific consideration to Hayflick's doctrine is itself a dead-end path.

The editors of *Experimental Cell Research*, who devoted 36 pages to the 1961 article, and 22 pages to the 1965 article, bear a portion of responsibility for publishing ridiculous, illogical, unfounded, and simply false statements; it would be hard to identify any standard of quality that was followed in accepting those articles for publication. The mass media can't be blamed too much in this case, because the scientific media themselves have been manipulated.

To talk about "reversing aging" by adding telomerase to cells reminds me of the advertisements for an apparatus that allowed you to recline with your head lower than your feet, except that when you age upside down, by lying around on that device, there is a silly grain of truth in the claim that you have "reversed" the aging process.

The fact that cells are always open to "reprogramming," which simply means responding appropriately to their environment, is an important thing to keep in mind. Alexis Carrel's experiments are still the best demonstration that biological aging is essentially a response to something in the cells' environment. Carrel's emphasis on fats as an important aspect of aging is massively supported by research in nutrition, organ transplantation, and tissue culture.

It is now clear that estrogen is intimately related to the universal stress-reaction system, the heat shock proteins. Progesterone, the most direct and general antagonist to estrogen, is now seen to be involved in this fundamental system--it opposes the actions of the stress proteins, and the stress proteins mediate the factors which cause a progesterone deficiency.

Progesterone, thyroid, saturated fats, and light are primary antistress factors which have already been shown to protect against some of the effects of aging (such as autoimmune

Les H.S.P testo et estro shift la différenciation cell vers dédifférenciation

reactions), and against the stresses which contribute to aging, and in many cases to reverse age-associated changes that have already occurred (such as regenerating the thymus). To fully reverse aging we need to know all of the factors that cause it; Dolly is proof that adult cells are not, in themselves, "old," and is confirmation that Carrel was on the right track.

Antipenko AYe, Antipenko YN, Adv Enzyme Regul 1994;34:173-198, "Thyroid hormones and regulation of cell reliability systems," Institute of Physiology, St. Petersburg University, Russia. "Data and arguments are presented that provide evidence of a role played by thyroid hormones (TH) in **cell reliability improvement. This role may be determined by synergistic TH action on the following key cell reliability systems: (1) reactive oxygen species (ROS) attack inhibition, and (2) genetic structure repair from injuries inflicted in the course of endogenous and induced mutagenesis**. (1) New approaches to ROS oxidation defence were examined. It has been shown that Ca(2+)-ATPase and, probably, regulatory proteins of cell membranes may be the main target for oxidative attack. Protein phosphorylation as well as use of dithiothreitol will lead to a protective action against Ca2+ transport damaging in aorta smooth muscle sarcoplasmic reticulum under oxidation by HOCl, the most toxic ROS of activated neutrophils, whereas thyroxine (T4) and 3,5,3'-triiodothyronine (T3) validly inhibit chemiluminescence in human neutrophils activated by pyrogenal, a lipopolysaccharide from Salmonella typhi cell wall. As this takes place, TH most likely block neutrophil stimulation at the receptor-ligand interaction level. In this case L-T4 and L-T3 antioxidative effect is greater than that of DL-thyroxine and much greater than that produced by such a potent antioxidant as 4-methyl-2,6-diisobutyl phenol. (2) **T4 acts as reparogen in rat liver cells under X-ray irradiation when a dose measuring one-half of daily hormone production by the normally functioning thyroid gland is administered to animals.** Ionizing radiation dose reduction factor reached 1.3-1.4 following T4 administration. **Reparogenic effect of T4 persists for at least 2 months from the moment the hormone has been administered** and can be reduced in the presence of dinitrophenol. **It is important to note that antioxidant and reparogenic TH potential can manifest itself within the range of physiologic concentrations of these hormones. Therefore, stimulation of cell reliability systems with TH may prove to be important for correcting conditions caused by errors in energy- and Ca(2+)-dependent DNA repair under extensive ROS attack**. In particular, taking into account different responsiveness of normal and neoplastic tissues to TH, the use of TH reparogenic as well as antioxidant potential may contribute significantly to the improvement of antitumor radiotherapy efficacy.

Baraboi VA, Nikiforova NA, Moskalenko IP, Radiobiologiia 1990 May;30(3):305-307, "[The ability of peripheral blood lymphocytes to repair DNA and the survival of rats].[Article in Russian]," "Individual and group differences were revealed in the capacity of rat peripheral blood lymphocytes of DNA repair in response to the DNA damaging test-effect of irradiation in vitro. The survival rate of rats irradiated with a dose inducing 50-per cent death was in a definite relationship with the repair capacity of blood lymphocyte DNA in each animal individual prior to irradiation."

Byrne E, Dennett X, Trounce I, Rev Neurol (Paris) 1991; 147(6-7):532-535. **"Oxidative energy failure in post-mitotic cells: a major factor in senescence." "A significant decline with age in state III respiration rates has been documented in man and experimental animals in several tissues."** Focal areas of cytochrome oxidase negativity, resembling those in skeletal muscle fibres in patients with chronic progressive external ophthalmoplegia (CPEO) syndromes, appear in old age. The mitochondrial genome is susceptible to mutation because of a high turnover rate, ineffective DNA repair mechanisms and a hostile environment rich in free radicals. The available data supports the development of mitochondrial failure in old age in fixed post-mitotic tissues suggesting that mitochondrial failure may be central to the senescent process."

Mydlarski MB, Liberman A, Schipper HM, Neurobiol Aging 1995 16(6):977-981, **"Estrogen induction of glial heat shock proteins: implications for hypothalamic aging."** "In the aging mammalian hypothalamus, a unique subpopulation of glial cells accumulates peroxidase-positive cytoplasmic inclusions distinct from lipofuscin. In adult rodents, this senescence-dependent glial granulation is accelerated by administration of estradiol valerate. In the present study, brain sections derived from male rats given 3 monthly intramuscular injections of estradiol valerate (0.2 mg or 2.0 mg) were immunostained for heat shock proteins and glial fibrillary acidic protein to determine

whether a glial stress response is implicated in estrogen-induced granulation. **Our findings indicate that estrogen elicits a heat shock response and subsequent granulation in astrocytes residing in estradiol receptor-rich brain regions including the arcuate nucleus and the wall surrounding the third ventricle but not in estradiol receptor-deficient regions such as the striatum and corpus callosum. The heat shock proteins induced by estrogen, namely, the 27, 72, and 90 kDa stress proteins, are upregulated in astrocytes in response to oxidative challenge supporting our hypothesis that estrogen mediates senescent changes in the rodent hypothalamus through oxidative mechanisms."**

Gospodarowicz D; Hirabayashi K; Giguère L; Tauber JP, "Factors controlling the proliferative rate, final cell density, and life span of bovine vascular smooth muscle cells in culture," J Cell Biol, 1981 Jun, 89:3, 568-78 "Low density vascular smooth muscle (VSM) cell cultures maintained on extracellular-matrix(ECM)-coated dishes and plated in the presence of either plasma or serum **will proliferate actively when serum-containing medium is replaced by** a synthetic medium supplemented with three factors: high density lipoprotein (HDL, 250 micrograms protein/ml); insulin (2.5 micrograms/ml) or somatomedin C (10 ng/ml); and fibroblast growth factor (FGF, 100 ng/ml) or epidermal growth factor (EGF, 50 ng/ml). The **omission of any of these three factors from the synthetic medium results in a lower growth rate** of the cultures, as well as in a lower final cell density once cultures reach confluence. When cells are plated in the total absence of serum, transferrin (10 micrograms/ml) is also required to induce optimal cell growth. The effects of the substrate and medium supplements on the life span of VSM cultures have also been analyzed. **Cultures maintained on plastic and exposed to medium supplemented with 5% bovine serum underwent 15 generations. However, when maintained on ECM-coated dishes the serum-fed cultures had a life span of at least 88 generations. Likewise, when cultures were maintained in a** synthetic medium supplemented with HDL and either FGF or EGF, an effect on the tissue culture life span by the substrate was observed. Cultures maintained on plastic underwent 24 generations, whereas those maintained on ECM-coated dishes could be passaged repeatedly for 58 generations. These experiments demonstrate the influence of the ECM-substrate only in promoting cell growth but also in increasing the longevity of the cultures."

Kondo M, Tamaoki J, Sakai A, Kameyama S, Kanoh S, Konno K., Am J Respir Cell Mol Biol 1997 16(1):62-68. "Increased oxidative metabolism in cow tracheal epithelial cells cultured at air-liquid interface." "Airway epithelial cells cultured at the air-liquid interface possess highly differentiated functions and structures compared with the cells cultured under immersion. We examined the oxidative metabolism and glycolysis in cow tracheal epithelial cells on Days 3, 6, 10, and 13, cultured under three different conditions: (1) immersion culture on porous filters with apical and basolateral feeding (IM), (2) air-exposed culture on porous filters with basolateral feeding, i.e., air-liquid interface culture (AI), and (3) conventional immersion culture in plastic dishes with apical feeding (DI). **Lactate production was less in AI than in IM and DI on Day 3 through Day 13, whereas cellular adenosine triphosphate content and basal O2 consumption were greater.** Ouabain-sensitive and ouabain-insensitive O2 consumption, and the uncoupled O2 consumption were also greater in AI. Cytosolic lactate dehydrogenase activities on Day 10 were lower in AI, whereas alpha-ketoglutarate dehydrogenase activities were higher. The increased oxidative metabolism in AI was more pronounced at the late phase of culture (Days 10 and 13). In contrast, glycolysis remained elevated during the experiment in IM and DI. These data suggest that (I) AI begins to promote oxidative metabolism from growth phase by the provision of adequate oxygenation, and then further shifts to oxidative metabolism with differentiation; and (2) apical feeding may be responsible for the disturbance of the development of the oxidative metabolism."

Lambert B, Ringborg U, Skoog L, Cancer Res 1979 39(7 Pt 1):2792-2795. "Age-related decrease of ultraviolet light-induced DNA repair synthesis in

human peripheral leukocytes," "The capacity for ultraviolet light-induced DNA repair synthesis, studied in peripheral leukocytes from 58 healthy subjects 13 to 94 years old, was found to vary greatly between individuals. A negative, statistically significant correlation was obtained between age and this synthesis, indicating a decrease in repair capacity with age. An age-related decrease in DNA repair may increase the susceptibility of cells to agents causing DNA damage, i.e. carcinogens and certain cytostatic drugs."

O'Brien SN, Larcom LL, Baxley EG, Horm Res 1993; 39(5-6):241-246. **"Correlates of plasma cortisol and DNA repair in human peripheral lymphocytes: suppression of repair in women taking estrogen."** "We have examined the relationship between total plasma cortisol concentration and DNA repair capacity in human peripheral lymphocytes cultured in vitro; the data indicate that high concentrations of cortisol (> 20 micrograms/dl) inhibit DNA repair. The inhibitory effect can be abrogated by the addition of RU38486, a cortisol antagonist. In addition, we compared plasma cortisol concentration and in vitro DNA repair capacity in 52 healthy individuals. **Females on therapeutic estrogen (oral contraceptive or estrogen replacement therapy) had significantly elevated plasma cortisol and suppression of DNA repair capacity."**

Pershadsingh HA, Martin AP, Vorbeck ML, Long JW Jr, Stubbs EB, Jr., J Biol Chem 1982 257(21):12481-12484. "Ca2+-dependent depolarization of energized mitochondrial membrane potential by chlortetracycline (aureomycin)." "The addition of chlortetracycline (CTC) to succinate-energized rat liver mitochondria resulted in depolarization of the membrane potential and **decreased respiratory control**. CTC inhibited both processes at concentrations that were half maximally effective at approximately 13 and 16 microM, respectively. These inhibitory effects were prevented by either the Ca2+ chelator, ethylene glycol bis(beta-aminoethyl ether)-N,N,N',N'-tetraacetic acid, or the inhibitor of mitochondrial Ca2+ influx, ruthenium red. These findings are consistent with the formation of a membrane associated calcium-CTC complex and suggest that CTC can alter mitochondrial energy metabolism during transmembrane Ca2+ cycling."

Smith ME, Larcom LL, Freeman SE, Chem Biol Interact 1985 Aug;54(3):325-335 "Serum effects on DNA repair in human cells." "Freshly isolated human lymphocytes were used to determine how serum supplements affect cellular capacity to repair UV damage. **Repair capacity was always found to be greatest in medium supplemented with autologous plasma. Variability in repair capacity among individuals was greater in serum supplemented medium than in unsupplemented medium. Thus, in vitro cellular responses will most accurately represent in vivo responses if autologous serum factors are present in the culture medium. This is of particular importance in studies attempting to correlate DNA repair capacity with age or susceptibility to carcinogenesis."**

Piotrowicz RS, Weber LA, Hickey E, Levin EG., FASEB J 1995 Aug;9(11):1079-1084, "Accelerated growth and senescence of arterial endothelial cells expressing the small molecular weight heat-shock protein HSP27." "Bovine arterial endothelial cells were stably transfected with the human wild-type (wt) HSP27 or a mutant gene (mu) encoding a nonphosphorylatable form of the protein. At early passage both cultural and cellular morphology were similar, although the vacuole content in wtHSP27 was much higher than muHSP27 cells. **As the cultures aged, wtHSP27 cells became large, polymorphic, highly vacuolated, and reached senescence before muHSP27 transfected cultures, which remained small and polygonal with few detectable vacuoles.** Vector control cells showed an intermediate phenotype. Tritiated thymidine incorporation studies were performed with multiple wtHSP27 and muHSP27 clones and the results compared with 11 vector control clones. The results showed an average increase in growth rate for the wtHSP27 cells of 3.0 +/- 0.6 times. The growth rate of eight muHSP27 clones showed a slight decrease. **Estradiol treatment of endothelial cells resulted in an increase in both bovine and human HSP27,** with peak expression at 100 nM. Treatment of the vector-transfected cells with 100 nM estradiol resulted in a 1.44 +/- 0.18 fold increase in growth rate, which was blocked by expression of muHSP27. **These data demonstrate a role for HSP27 in controlling the growth rate of endothelial cells in an estrogen-responsive manner."**

Tang PZ, Gannon MJ, Andrew A, Miller D, Eur J Endocrinol 1995 133(5):598-605, "Evidence for

oestrogenic regulation of heat shock protein expression in human endometrium and steroid-responsive cell lines." "**HSP 70a and HSP 90 alpha expression were stimulated by oestradiol. Progesterone generally depressed HSP 90 alpha expression and simultaneous addition of both oestradiol and progesterone to the culture medium was antagonistic to HSP 90 alpha expression**."

Wolffe AP, Glover JF, Tata JR, Exp Cell Res 1984 Oct;154(2):581-590 "**Culture shock. Synthesis of heat-shock-like proteins in fresh primary cell cultures.**" "The isolation of Xenopus liver, lung and testis cells by collagenase digestion of the tissue, followed by Percoll density gradient centrifugation, was characterized by the **preferential synthesis of two proteins whose size and charge were similar to 70 and 85 kD heat-shock proteins.** The synthesis of these two heat-shock-like proteins, relative to that of total protein, declined gradually in the first 3-4 days after the cells were plated out for primary culture. In fresh primary cultures of liver parenchymal cells **albumin mRNA concentration declined rapidly** and plateaued at 3-4 days of culture. Freshly isolated male Xenopus hepatocytes were refractory to induction by estrogen of vitellogenin gene transcription but they reacquired hormonal response during the first 3 days of culture. Both of these differentiated phenotypic functions of the Xenopus hepatocytes were quantitatively associated with the decline in synthesis of hsp-like proteins in freshly prepared primary cell cultures. Freshly isolated or heat-shocked hepatocytes exhibited a rounded shape with little intercellular contacts, whereas during the recovery period of 3 days they acquired a flattened shape with a high degree of intercellular and cell-substratum interaction. These results present the first evidence for the **preferential synthesis of heat-shock-like proteins by procedures for establishing primary cell cultures. They emphasize the necessity of monitoring normal and heat-shock protein synthesis and cell morphology before using primary cell cultures for studying normal regulatory and developmental processes.**"

Wu WX, Derks JB, Zhang Q, Nathanielsz PW, Endocrinology 1996 137(12):5685-5693 "Changes in heat shock protein-90 and -70 messenger ribonucleic acid in uterine tissues of the ewe in relation to parturition and regulation by estradiol and progesterone," "Steroid receptors, including estrogen receptor (ER) and progesterone receptors (PR), form associations with heat shock proteins (Hsps). **Dissociation of Hsps activates PR, whereas retention of Hsp90 in vitro stimulates ER**. Progesterone and estrogen, interacting with their receptors, regulate myometrial contractility throughout pregnancy and during parturition. We hypothesize that uterine ER and PR changes concurrent with changes in Hsp90 and -70 abundance could alter uterine function." "Dramatic tissue-specific increases in Hsp90 and -70 mRNA were observed in myometrium and endometrium ($P < 0.05$) during spontaneous and glucocorticoid-induced labor. Hsp90 and -70 mRNA localized in myometrial, arterial smooth muscle, and endometrial gland epithelial cells. Estradiol increased Hsp90 and -70 mRNA in myometrium and endometrium of nonpregnant ewes. Progesterone did not affect Hsp90 and -70 mRNA abundance, but **inhibited the estradiol-stimulated increase.** These data support our hypothesis that at term, increased abundance of Hsp90 and -70 may inhibit uterine PR and stimulate ER function in uterine tissues. Similar changes, if present, would be of importance in species showing no progesterone withdrawal before labor, such as primates, including pregnant women."

Zeman EM, Pearson CI, Brown JM, Radiat Res 1990; 122(1):72-76, "**Induction of hypoxia in glass versus Permanox petri dishes,**" "The survival of Chinese hamster ovary cells in culture following graded doses of X rays delivered under aerobic and hypoxic conditions, or treatment with the bioreductive drug SR 4233 under hypoxic conditions, was evaluated as a function of whether cells were plated onto glass or Permanox plastic petri dishes. In the case of treatment with SR 4233, the influence of varying the total volume of medium in the dishes was also studied. While the **Permanox petri dishes were sufficient to yield "radiobiological" hypoxia,** that is, oxygen enhancement ratios of approximately 3.0 were obtained for X irradiation, they were inferior to glass petri dishes with respect to the hypoxia-selective cytotoxicity of SR 4233. For a 90-min hypoxic exposure to 40 microM SR 4233, the surviving fraction of cells plated on plastic dishes averaged about 50-fold higher than that of cells plated on glass dishes. Although varying the total medium volume did affect the extent of SR 4233-induced cytotoxicity for glass dishes--drug toxicity decreased slightly with increasing medium volume--this was not the case for the plastic dishes, in which the cell survival following a fixed SR 4233 exposure was essentially constant as a function of medium volume. These results suggest, at least for SR 4233, and under these experimental conditions, that Permanox petri dishes are not satisfactory for such studies."

Ray Peat's Newsletter

Copyright 2003 Raymond Peat P.O. Box 5764, Eugene, OR 97405 September 2003

I wrote this several years ago, but each month there was always something more topical to send out. Every day, the mass media publicize and promote dangerously mistaken ideas, so there was always a more urgent seeming topic.

I always try to place concrete subjects in their most appropriate context. As a person who studied and worked in linguistics, literature, and art before concentrating on work in biology and physiology, I realize that language, imagery, and metaphor always work within a specific cultural setting. Seemingly infinite amounts of money can be mobilized by strong metaphors. The War on Cancer, the War on Drugs, the Genome Project, are examples of using language deviously to manipulate the public. Every issue, scientific or political, to be considered sanely, requires that we look critically at the contexts, and the contexts include the words, the concepts, and the metaphors that we use to communicate with.

Culture is the context for political power. **I have often discussed topics in biomedical research which reached their highest achievements in the first half of the 20th century, and then declined in the second half of the century, under the influence of the pharmaceutical industry, and its servant, the U.S. F.D.A., but this was only one aspect of a general process.**

A great and deliberate pollution has been spread through world culture. While the U.S. Government was secretly using Americans as guinea pigs for experiments with radiation and germ warfare, it was secretly spending vast amounts of money (most of it from the Marshall Plan) to support Abstract Expressionism in painting, and parallel movements in other arts and sciences. The CIA-funded Congress for Cultural Freedom was representative of the way this public money was used to eliminate freedom of expression. "Liberals" and "progressives" were special targets for this manipulation, but even conservatives such as Henry Luce (publisher of *Time* and *Life*) were induced to stop ridiculing Abstract Expressionism, and to begin supporting it.

The suppression of critical judgment in art makes it easier to suppress it in science, medicine, and politics.

I. Public Passivity and the Screw
II. Phenomenology of the State: Marxism according to Groucho
III. Education for the Primacy of Paranoia

I.

The sports hero, the "world class performer," the producers of grand spectacles, by definition are "excellent," better than everyone else at what they do. When the culture is filled with grand achievements, admiration is an appropriate reaction, and participation isn't. Almost the whole population falls between the Olympics and the Special Olympics, in all sorts of abilities, but their culture is created from the top down. Similarly, small businesses are squeezed out by monopolies, craftsmen are replaced by computer programs, insurance companies regulate the professions. And as excellence becomes a theoretical standard, everyone's performance is debased. The "quality" that people like Donald Trump admire is unlike the qualities that people used to enjoy.

"Freedom is not a concept in which people can do anything they want, be anything they can be. Freedom is about authority." ***Mayor Giuliani, New York Times, March 17, 1994***

Several years ago our local newspaper and television music critics raved about the "acoustics" of the city's new 22 million dollar concert hall. I had always wanted to hear Yehudi Menuhin play, so when he came to town I got a seat up near the ceiling, where I was startled to find that the sound was coming out of loudspeakers mounted in the ceiling. Electronically processed sound, generated by vibrating metal and plastic loudspeakers, can be heard even better at home, without the "acoustics" of the concert hall.

The "quality" is in the minds of those impressed by the cost of the building.

The words "client" and "patient" express the passivity of the customer in relation to the lawyer or physician. The same passivity exists wherever "expertise" replaces self-reliance. The individualism that was idealized in America has been replaced by a client mentality.

The authority of power can't be questioned if the people don't have their own knowledge, ability, and power.

II.

History attempts to make time coherent, logic tries to transcend the incoherence of history, and phenomenology tries to find meaning, purpose, and motive in the incoherence and illogicality of our social experience, primarily by eliminating false assumptions. Governments and their educational systems are in the business of preserving false assumptions.

The theory of monarchy is that only one person has to think, so the citizen-subject can be thoughtless. Other political philosophies are one-thoughted, two-thoughted, etc., depending on how little reality they admit. Hegel tried to get complexity organized into the simplifying monarchy of the thought of god. Marx took the idea of the dialectic, and used it to generalize reality, but underestimated the difficulty of clearly defining generalizations such as capital, when the boundaries of the system were in a continuous process of reformation.

When knowledge and culture become important parts of capital ("intellectual property," and judicially recognized "expertise" for example), the ambiguities demand that the contributions of Groucho Marx be considered as an extension of classical marxism. Groucho said he wouldn't want to belong to any club that would have him. To recognize the ambiguities of class and power is to begin to grasp the phenomena of society. Identity and belonging, language, concepts, names and origins seem more important than physical realities. And that fosters the growth of a culture of fraud and deception. Advertising, lobbying, and bribery blend smoothly with art, science, and law.

Any statement, no matter how clear and logical, depends on context--even scientific and mathematical statements. Goedl's principle and computer-program glitches illustrate the idea. Any statement demands a clarifying context, and therefore a dialog. That's the meaning of the "dialectic" introduced by Hegel and expanded by Marx. Everything has to be made clear by discussion. Reality is more complex than any attempt to formalize it. The reality is that laws and contracts function primarily as traps, to give the appearance of reason to acts of power. Contracts with insurance companies, publishers, and state agencies are famously meaningless, but *any* contract or law of importance is nothing but an opportunity for powerful groups to use the force of money and the courts (or police and their weapons) to defeat those who would assert some "right" under the law or contract.

"The most important Manhattan Projects of the future will be vast government-sponsored inquiries into . . . the problem of making people love their servitude."

"To make them love it is the task assigned, in present-day totalitarian states, to ministries of propaganda, newspaper editors and schoolteachers. But their methods are still crude and unscientific."

Aldous Huxley, 1946

People who consider themselves to be the state (whether or not they say "the State, it's Me") have almost an identity with the Law. Laws were written in the past, and since the past isn't accessible, it's almost as though a foreign power ruled us from a distant imperial capital, and sent its agents among us to apply the law to us as they see fit. They are agents of the state, interpreting the law for us, so that we may be bound to it. As soon as they perceive themselves to be agents of the state, their thought becomes the law.

The problem relates to social workers and lawyers as much as it does to presidents and attorneys-general--their subjectivity fills not only their world, but it intrudes into everyone else's

world. Lawyers and presidents lie, not just because they can get away with it, but because it has become part of the job description.

The basic question about the state is where its legitimacy comes from. The monarch used to speak for god, and his clergy backed him up. Republics kept the basic idea of the state, and invented a new story about its legitimacy. But the new government is always founded by traitors to the old government. Treason is the essence of the state. Treason is legitimacy.

The official implementation of the policy of Loyalty Oaths made it clear that the government of the United States aspired to totalitarian perfection. The same government had secret policies, secret laws, secret programs, and acknowledged that it had to lie to its citizens. Citizenship amounted to an arranged marriage between an eight year old virgin and a syphilitic pirate.

If everyone who is now in prison were released, and put into the jobs of government officials, filling them from the top down, and deciding among themselves who would go to congress, who to the executive branch, to the courts and state governments, nothing would get worse, and it might get better, because the question of legitimacy would be settled, and the cost of bribes and campaign expenses would be smaller.

Jury nullification is one of the few situations in our democracy in which democracy and reason can sometimes be seen in action, but it is limited by the way juries are constituted. People who are homeless can't serve on juries, and neither can people who need more to pay the rent than the $10 per day jurors commonly receive. Under Jim Crow laws, white people always tried black people. If juries really reflected the population in general, or if they were actually chosen from the peers of the accused (most prisoners are poorer than those who condemned them), fewer of those accused would be convicted.

Capital punishment, under our system, never punishes capital. If a corporation's officials deliberately take actions that they know will kill people, it has committed first degree or aggravated murder, and so its capital, all of its capital, should be taken from it, as well as from those who took the action. It is protested that "innocent investors would lose their money," but the protest makes evident the truth that corporations are designed to let people get away with murder for profit. If a corporation is to be anything but a conspiracy against the public, it must be fully responsible for its actions. Investors, to protect their money, would have to know what was going on in the corporation. This is exactly the principle that is now in practice regarding the confiscation of property involved in certain crimes, primarily drug crimes, but the reasoning would be even clearer if it were applied to the corporate property involved in corporate crimes.

The principle that no valid contract can be made to do something illegal takes legitimacy away from corporations--and governments--which are used to commit crimes, with simpler logic than that used in confiscating airplanes used to smuggle drugs. Likewise, a clause or implication of a contract which is secret from one of the parties to the contract is a logical impossibility, and makes the contract a nonentity.

If a corporation is a conspiracy against the public, with a prerogative to keep secrets for its own profit, any government which has any secrets from those it rules, is a conspiracy against them, for whatever reasons it might have. The right to have secret information is the right to lie, to rob, and to kill, and those who assent to such governmental power have no claim to legitimacy as citizens. Any governmental action which is kept secret constitutes evidence of the government's illegitimacy.

If power must be open to be legitimate, then the power to determine the intellectual content of any educational curriculum must be open. Governmental power is behind every recognized educational institution, but nearly all decisions about the accreditation of those programs are made in private. **If the reasons for imposing certain curricula were open to full discussion, then the educational programs would also be more likely to incorporate the principle of responsibility and evaluation.**

As funding for education shrinks, the state is seen to be exercising thought-control, in a simpler and more direct way, when it specifies the

curriculum that must be followed in home-schooling. When the state accredits educational programs, or establishes private accrediting agencies, it is delegating thought-control to the accredited, or accrediting, agencies.

If the state, through its accreditation system and its court system, can define what an expert is, then it can define what knowledge and truth are. The loyalty oath was the blunt object used by Adolph Hitler, Strom Thurmond, Richard Nixon, et al., to keep people in line. Education and its accreditation, backed up by a prison system, are the high-tech equivalent of the loyalty oath, controlling the intellectually limited public as effectively as the old system controlled the morally atrophied.

Approved knowledge is made tantamount to citizenship. Even beauticians have to be licensed by the state. Schooling is the moral equivalent of syphilis, but piracy is the prerogative of the corporate-bureaucratic elite.

As long as knowledge is power, and power is (able to define) knowledge, secrecy and ignorance will be promoted and knowledge will be rationed.

Schools are already in the business of rationing knowledge. The idea and practice of "challenging examinations," being able to get credit in a course if you already know what the course is supposed to teach, has essentially disappeared, because, as Oregon's Secretary of Public Instruction Gubser told me, "what students know doesn't have anything to do with education." In my dealings with other state, federal and private accreditation officials, I understood that to be their functional attitude, but when I heard the state's top official blurt it out after her evasions had failed to dissuade me, I realized that the system was consciously conspiring against knowledge. If people could get their diplomas just by proving their (conventionally recognized) knowledge, they would have too much time to spend learning about reality.

I have heard many teachers say that it is impossible to measure how much a student knows, and my question has to be, "then how can you know that?" And why are exams used to choose candidates for college admission, or to enter the practice of medicine or law, or to get a driver's license? Teachers, for whatever reason, function as part of the mystification that creates the knowledge rationing system. Alfred Jarry was describing schools and governments when he wrote about the "debraining machines."

The great danger now is that critical consciousness is becoming so rare, that the State will be able to extend the concept of "contempt of court" to the administratively punishable offense of "contempt for the legally constituted knowledge." The mechanisms already exist for doing this. Forty years ago, Wilhelm Reich was imprisoned, and his books were burned. *The Mass Psychology of Fascism,* which analyzed the dirty little character defects of authoritarian officials, was destroyed as a "label for a medical device." *The Murder of Christ, Listen Little Man, The Function of the Orgasm,* and other books about the nature of social oppression and violence were not even available to graduate students in psychology. The academic apparatus in its entirety conspired to maintain the official silence while Reich died in prison.

At least until it is illegal to do so, we should continue to ridicule, criticize, satirize, and condemn the state power which is in itself an abuse of reason and justice. Let there be a new world disorder!

The attitude toward the past is everything. The past, by definition, is unalterable, and can't be present again. Examining the record, we can see how we got where we are, but knowing where we are going is part of the life process itself. Blake said, "Imagination has nothing to do with Memory."

Those who try to "preserve the past," by trying to make it live again, in effect are trying to gain immortality by imposing death onto life.

Institutions are things that persist from the past, in someone's way of life and attitude, that are imposed onto life, over and over. Circumcision is a metaphor for every institution. The living flesh is trimmed, pain is inflicted, attitudes are repeated. "As the caterpiller chooses the fairest leaves to lay her eggs on, so the priest lays his curse on the fairest joys."

Logic that works for established knowledge can't work for projecting the future. Logic

clarifies and orders the past, but lived intelligence, imagination, is the mental tool that is appropriate for the future, which is the only place we can live.

We can get along very nicely without the debraining machines.

III.

If the schools and universities have the purpose of training people to be good employees, then only the first two years should be required, to teach reading and counting. At the age of 8 or 9, the practical career studies could begin, in engineering, medical services, judicial and military services, food preparation, and entertainment services.

But, if people were to be prepared to function as citizens, to make decisions about how their lives were to be lived, then the process of education would be based on criticism, evaluation, and on seeing things in all the relevant contexts that can be imagined. And the process of education and criticism would move toward the center of our lives, and would be continuous, from infancy to old age.

A wonderful variety of stupid beliefs has been propagated from the centers of academic power, and each type of stupid belief has tended to reign for a generation, until a new, more oppressive stupidity has been invented and imposed in its place. The impossible ideas can be propagated, because the educational system never learned how to teach people to recognize when the emperor's new clothes don't exist, and to say so.

When everyone is talking about the emperor's new clothes, the person who trusts his senses will perceive that a false belief is being propagated when he sees that the emperor is naked. To talk about the imposition of lies is to risk being classified as a "paranoiac." If everyone discussed the alternative interpretations that seem reasonable, then evidence would be evaluated in relation to theories and assumptions. **The basic violation of reason then would be the authoritarian refusal to discuss the issue.** Secrecy for national security would be recognized as the equivalent of a coup d'etat, taking authority away from the public. .

The culture of computation is a development of authoritarianism. Computers were conceived as mathematical machines, to work out the implications of premises. Mathematics was always popular with the established powers, because it never questioned assumptions. The computers that have been developed into manipulators of images also make the manipulation of people easier.

The "critical paranoia" that Salvador Dali described was the basic mental process that used to be called "wonder," guided by the critical evaluation of alternatives. The questioning curiosity aroused the speculative imagination, and the quality of the perception--the richness of the discovery--was suggestively related to its truth and significance.

To be concerned with the meaning of life and the quality of life is to wonder whether "this is all there is," and to live in a state of exploration. An educational system that is dedicated to the preservation of things as they are, must stifle that natural exploratory impulse. Because if it isn't stifled, that impulse will look for a better way of living. Our nature, so far, has been extremely antagonistic to our nurture, and from that opposition the system has created the ideas of original sin, corruption of the body, bad instincts, genetic determinism, neokantianism, professional training, and all of the other denials of essential human intelligence.

The nature of our biological development requires that the organism function and interact with the environment as it grows. Education of the intelligence is intrinsically related to the proper growth and function of the organism which is the person. The lack of stimulation or the wrong kind of stimulation makes us sick, ugly, and stupid. Schooling plays its part in degrading intelligence, but the whole culture is structured to warp our growth into forms that are convenient for the functioning of the system as it is.

The argument for realism and bottom-line practicality is often made, that accountants must be trained to help corporations grow, and that people would naturally prefer to learn something more pleasant than accounting, and so there must be extrinsic inducements and coercion. But the higher realism and practicality argues that human consciousness and existence must have priority

over any of the economic mechanisms that might support a particular way of living.

The priority of human intelligence specifies the means that are appropriate for education in any setting. Intelligence is, by definition, responsive, and responsive intelligence is necessarily responsible. The sources of power in a society are always integrated with the educational process, and the manipulative use of control has always made the process of education disappear.

The free use of education amounts to the attempt to solve the problems of society, and so education and intelligence would be of service to society. The universities in third-world countries have always been recognizable as servants of the ruling classes or imperialists, but Europe and the United States have fostered a perception that universities existed to serve the public and to educate for democracy.

If there were no secrets, power would be administered in the open, and there would be no conspiracies, or rather, the ubiquity of the process would be evident, and a different term would be used. But general awareness of the exercise of power--stupid as power's actions have always tended to be--would make things hard for those in power. And so any factor that fosters a suspicious, critical, imaginative, exploratory awareness and questioning of the world tends to weaken the concentration of power, and to share in the exercise of power. Intelligence, as far as it exists, tends to be revolutionary, and so education (if it is essentially an exercise and development of intelligence) must be devoted to the overcoming of stupidity, especially when stupidity rules.

==========

Frances Stonor Saunders, ***Who Paid the Piper: The CIA and the Cultural Cold War*** (London: Granta Books), 1999; ***The Cultural Cold War: The CIA and the World of Arts and Letters.*** New York: New Press, 2000.

Pages 397-404: Tom Braden, director of the International Organizations Branch of the CIA, said that by 1953, "we were operating or influencing international organizations in every field" (page 398). When the source of their funding was revealed many of the people claimed not to have known, but Braden shows that they had to have known.

A. C. Higgins, State University of N.Y., Albany, commenting on ***Creating the Cold War University: The Transformation of Stanford,*** Rebecca S. Lowen, Berkeley, California: The University of California Press, 1997:

"There's not a word in this book about fraud and dishonesty in science. What is abundantly clear however is the transition from the 20th century university to the "Cold War University," a transition which is necessarily accompanied by the loss of idealism and the core values of science. This new science is a prostitute variety, ready for any comer on the open market. What is important to the academic administrator of the Cold War University is the bottom line. Why should anyone expect honesty in such an institution? Indeed, it's no wonder that fraud and dishonesty are as common as they are. What is amazing is that honesty and morality remains at all! It's now been 40 and more years since "entrepreneurial science" was substituted for the older stuff. After 4 decades, is anything of pure science left? Should we be surprised at anything that happens?"

Ivan Illich, from the introduction to ***Tools for Conviviality,*** 1973:

"Our analysis of schooling has led us to recognize the mass production of education as a paradigm for other industrial enterprises, each producing a service commodity, each organized as a public utility, and each defining its output as a basic necessity. At first our attention was drawn to the compulsory insurance of professional health care, and to systems of public transport, which tend to become compulsory once traffic rolls above a certain speed. We found that the industrialization of any service agency leads to destructive side effects analogous to the unwanted secondary results well known from the overproduction of goods. We had to face a set of limits to growth in the service sector of any society as inescapable as the limits inherent in the industrial production of artifacts. We concluded that a set of limits to industrial growth is well formulated only if these limits apply both to goods and to services which are produced in an industrial mode. So we set out to clarify these limits."

"The only source of knowledge is experience."

Bioelectric Fields, Regeneration, and the Lactic Acid Myth

Exercise physiologists, knowing that lactic acid is produced during intense exercise, and cancer biologists (especially since Warburg's work showing that all cancers have a respiratory defect) who know that cancer tends to produce lactic acid, almost always talk about the "acidity" of the fatigued muscle or of the cancer cell.

While it is true that the entry of lactic acid into the blood tends to produce metabolic acidosis, the cell which is producing the lactic acid is actually more alkaline than normal cells. The simplest way to think of it is that "acid leaving the muscle makes it less acidic." But still, even though the chemical formula for producing lactic acid directly shows the consumption of acidity, and direct measurements confirm that the cells become more alkaline when they produce lactate, the average biochemist or physiologist is likely to think the opposite.

What we call inflammation offers a good conceptual link between the studies on excitotoxicity or cellular stress, and the newer approaches to the treatment of aging and degenerative diseases, based on ideas of regeneration and development. Controlling inflammation becomes part of promoting regeneration. Injury potential and inflammation are closely related; for example, I found that sunburned skin, or skin irritated by the application of a prostaglandin, had a negative polarity relative to normal adjacent skin.

Lactic acid (or its ion, lactate) is involved in stress, aging, edema, inflammation, rheumatic diseases, bioelectricity, nerve-muscle interactions, cancer, and the antiinflammatory actions of the thyroid hormone, among other things, so a fundamental confusion about what it does to cells means that much of biological and medical opinion has been unfounded. When I discussed the cellular alkalinizing effect of lactic acid formation in my dissertation in 1972, it wasn't a matter of scientific dispute, and since then, the newer techniques of measurement have made the situation even clearer. But, even today, almost always when conclusions are drawn about muscle fatigue, cancer, radiation damage, etc., they are based to a large extent on the false assumption about lactic acid and cellular pH. A specialist too often builds on the generalizations that are propagated by textbooks and other mass media.

When the pH of a cell or tissue changes, its electrical properties change.

In the normal body, repair is going on constantly, and generally the new substance conforms to the existing pattern. The systems of signals that govern these patterns are called 'developmental fields,' and during the last 80 years, evidence has accumulated showing that electrical fields participate in these processes of organization. (Child, 1921; McCaig, 1996.)

There is an electrical field around organisms and, internally, electrical fields contribute to the development and maintenance of anatomical structure. Sharks are able to find small fish buried under sand by detecting their electrical fields; they will dig for electrical devices that have similar fields. Large electrical fields have been demonstrated extending away from the surface of skin, and since these fields have some of the properties of a "static electrical field," many people have assumed that the charge was just something that passively accumulated by friction.

Le champ est alligné les molecule de la substance à ce donne une charge Polarizé

But an experimenter demonstrated the presence of an electrical field extending outward from the external surface of pieces of skin grown in a culture dish. When cyanide was added to the medium, blocking respiration, the field collapsed, and when the cyanide was washed out of the skin, allowing respiration to continue, the field reappeared. The intensity of respiration clearly governs the intensity of the field. The researcher suggested that the field had the characteristics of an "electret" field. An electret is a charge polarization that results when the molecules of a substance (wax or ceramic) are aligned by an external field while at a relatively high temperature, and then cooled.

He implied that the energy of respiration was causing an alignment of molecules, resulting in the polarization of charges. Any field of this sort will influence other charged particles, and so it is obvious that it will participate in the arrangement and organization of particles. The existence of such fields probably influences the alignments of particles within cells, and of cells within organs. There is a tremendous difference in the strength of the field produced by different individuals, but the pattern is always essentially the same, except when it is distorted by pathological conditions; tumors, for example, distort the field.

In general, cell excitation or stimulation increases the intensity of cellular respiration, but when oxygen isn't available, the stressed or dying cell may become hyperactive. Epileptic seizures, for example, can be produced by hypoxia or hypoglycemia, as well as by other stimuli such as imbalances of salts and water.

Textbooks often represent cellular electricity with a diagram showing the outside of a cell as "positive" relative to the "negative" inside of the cell. And researchers who have read those textbooks uncritically sometimes speak of the "positive" charge or field outside a cell. I'm sure they won't feel humiliated if I point out that the whole thing is an artifact of their experimental setup. Isolated cells in a liquid will move toward the positive pole in an electrical field, showing that the cell outwardly has a negative charge. This is called the sigma potential, or surface potential. And if the cell is pulverized, again, nearly all of its large molecular componenents and organelles will move toward the positive pole.

When an electrode is poked into a cell, it registers a negative polarity relative to the neutral outside. On a larger scale, if you put one electrode on moist skin, and put another electrode on a cut, the cut skin will be negative relative to the intact skin. This is called an "injury potential." But the intact skin is itself negatively charged, in the same way that any whole cell is negatively charged.

It has been suggested that sharks are attracted to wounded animals by the electrical field caused by the injury, rather than by the odor of the blood, since they can detect the injured animal from distances far beyond the spread of chemical substances from the blood. The animal's "injury potential" is apparently just an intensification of the animal's normal electrical field. (Although much of the research on electrical sensing has been done on fish, I suspect that land animals sometimes use electrical sensing. For example, dogs can sense an impending epileptic seizure of their owner; the electrical fields created--by the brain or the skin--during an extreme metabolic disturbance might be larger than those of a small fish buried under sand. People are able to detect the flow of a weak current in a buried wire, as discussed by Barnothy and Barnothy in *Biomagnetics.)*

I have seen articles in major science journals that draw important conclusions from the nonexistent positive charge supposed to be on the outside of cells, and those things have got past the editors and referees because those ideas are so current in our scientific culture. Less blatant, but equally false, ideas are even more prevalent. The use of various microelectrode techniques has produced an abundance of information on cellular electrical responses, but with the exception of the work of Gilbert Ling and a few others, the meaning of the data is obscured by a huge culture of phantasy theories.

With this sort of fundamental confusion about bioelectricity, it isn't surprising that there is so little interest in the morphogenetic influences of

L'intensité de la respiration cause un alignement des molecules ce qui resulte en Polarization des charges

excitation ou stimulation ↑ l'intensité de la respi, mais si l'oxygène n'est pas disponible les cellule mourant ou stressé peuvent devenir hyperactive

electrical fields. The textbook images of "membrane potential" give the impression either that relevant fields don't exist, or that they are the opposite of those observed experimentally, and those mistaken textbook images overwhelmingly dominate the scientific-political-economic scene.

The overall charge on proteins and other macrolecules is, in general, a matter of the pH of their environment. Usually, cellular proteins have a negative charge above a pH of 5. The ionization of chemical groups such as hydroxyl, amino, and sulfhydryl are responsible for the overall charge. The degree of oxidation or reduction affects the number of sulfhydryl groups, and the structural state of the protein also influences the charge. At high pH the charge is high, and the number and arrangement of sulfhydryl groups can affect the charge. The presence of small ions, carbon dioxide, and oxygen also influence the charge of proteins. When the whole living system is involved, bioelectricity interacts with other electron-related phenomena, including oxidation-reduction, pH, donor-acceptor and free radical reactions.

When the pH of blood is high, the cells of blood vessels are excited into contraction. When the pH of the blood is low, nerve activity can be dulled to the point of coma, as in diabetic acidosis. I think these effects of pH, and the simpler effects of pH on protein charge, are closely related to each other, and to the phenomenon of the injury potential.

Since proteins are generally negatively charged, and tend to move toward the positive pole when they are in an electrical field, a membrane made up of proteins (sheets or layers of cells, for example) will move in the same direction relative to the water that permeates it, meaning that the water will move in the opposite direction, i.e., toward the negative pole. This is called electroosmosis. Since the electrical charge on proteins becomes more strongly negative when the pH is high, and less strongly negative when the pH is low, water will tend to move across membranes from acidic regions into alkaline regions.

The contracting muscle tends to take up water, and forcing it to take up water increases its tendency to contract.

Oxygen, producing carbon dioxide, acidifies the cell, and carbon dioxide influences the cell's handling of water. Carbonic anhydrase inhibitors are commonly used to regulate conditions involving edema, including adaptation to high altitudes.

During intense contraction, especially when oxygen and carbon dioxide are limited, muscles produce lactic acid, and **the specific reaction in which lactic acid is formed causes protons to be consumed, that is, it raises the pH.**

Increased pH, decreased osmolarity, and the associated movements of ions increase the cell's excitability.

Because of the long history of thinking of muscle fatigue and hypoxia in terms of lactic acid production, and the mistaken idea that intracellular pH is more acidic in proportion to the production of lactic acid, the confusion of biolectrical ideas has been compounded by the confusion about pH.

Cellular excitation, exhaustion, and injury will affect the cell's electrical fields in different ways depending on the availability of oxygen, glucose, salts, etc., but **in each of those states, there is increased entry of calcium into the cytoplasm.**

Calcium's entry into cells in itself can lead to increased excitation (muscle contraction, cramps, and seizures, for example), to cell death, or to increased proliferation. (It has also been thought that sodium and water can stimulated proliferation. For example, Berman, et al., 1995.)

Something as simple as reducing the pH can prevent apoptotic ("organized" or "programmed") cell death. (K.P. Hanson and V. E. Komar, *Molecular Mechanisms of the Radiation Death of Cells,* Energoatomizdat, Moscow, 1985).

Carbon dioxide, produced by respiration, and ATP hydrolysis, are two powerful acidifiers of the cell; with sufficient stimulation both can probably act simultaneously, and in this situation the pH decrease will tend to oppose the exciting stimulus. Without sufficient oxygen to make CO2, a given stimulus might cause greater excitation and probability of death. The insufficiency

of oxygen also leads to a relatively reduced state of the cytoplasmic proteins, increasing their electrical charge at a given pH. **CO2 has many other effects that act in the same protective direction, such as calcium removal, iron binding, and water binding,** and these other effects are at least as important as the pH effect. (Badylak and Babbs, 1986 showed that the combination of a calcium blocker and an iron chelator with carbon dioxide tripled the survival after 7 minutes of cardiac arrest.) Adequate CO2 is intimately involved in the disposition of calcium, and calcium's regulatory significance is universally recognized.

K. P. Buteiko believed that increased carbon dioxide in the body fluids sometimes caused cancers to disappear. In many studies over the last 40 years (and the trend can also be seen in insurance statistics published in 1912), it is clear that cancer mortality is much lower at high altitude. Under all conditions studied, the characteristic lactic acid metabolism of stress and cancer is suppressed at high altitude, as respiration is made more efficient. The Haldane effect shows that carbon dioxide retention is increased at high altitude.

Studying athletes at sea level and at high altitude, it was seen that less lactic acid is produced by maximal exercise at high altitude than at sea level. Since oxygen deficiency in itself tends to cause the formation of lactic acid, this has been called the "lactate paradox"; the expectation was that more lactic acid would be formed, yet less was produced. Something was turning off the production of lactic acid. Normally, it is oxidative respiration that turns off glycolysis and lactic acid production, so that in exercise beyond the ability of the body to deliver oxygen, and in cancer with its respiratory defect, glycolysis produces lactic acid. So, something is happening at high altitude which turns off glycolysis.

The Haldane effect is a term for the fact that hemoglobin gives up oxygen in the presence of carbon dioxide, and **releases carbon dioxide in the presence of oxygen.** It is the increased retention of carbon dioxide that accounts for the "lactate paradox." Carbon dioxide activates the Krebs cycle, but it also combines with ammonium, and in doing so, deactivates glycolysis because ammonium activates a regulatory enzyme. At high elevation, carbon dioxide is retained, and lactic acid formation is suppressed. (This is called the Pasteur effect, but altitude physiologists haven't begun thinking in these directions.) Comparing very low altitude (Jordan valley, over 1000 feet below sea level) with moderate altitude (620 meters above sea level), ACTH was increased in runners after a race only at the low altitude, **indicating that the stress reaction was prevented by a moderate increase of altitude.** (el-Migdadi, et al., 1996.)

The perspective we get on cancer, from the high altitude studies, allows us to go beyond the specific issue of cancer, to the more general issue of stress and regeneration. In outline, stress alters the physical nature of the cellular substance in a way that activates the cell, in which case it will either die from exhaustion, or grow into new cells. The replacement of injured cells means that mutations need not accumulate, and this renewal with elimination of mutant cells has been observed in sun-damaged skin. Among the many layers of form-generating and form-sustaining systems, the balance of electrical fields has a basic place.

Several investigators have demonstrated that internal cancers altered the external electrical polarity of the animal, increasing the negative polarity in a region near the tumor. In the late 1960s, I suspected that irritation or inflammation created an injury potential, similar to the "demarcation potential" of a cut nerve or muscle. I covered one arm so that a small spot would sunburn without exposing the surrounding skin, and in other spots I applied small amounts of prostaglandins, the "hormones" derived from unsaturated fatty acids. The sunburned area was distinctly negative relative to adjacent areas, and some of the prostaglandins (PGF, for example) produced a slight increase of negative charge. I think these changes reflect both intensified metabolism and increased pH caused by interfering with efficient cell metabolism. Lactic acid

production raises the pH, and high pH increases the ionization of most proteins.

The localized distortion of the electrical fields will participate in adjustments that should tend to restore the normal fields, with different processes occurring depending on how long the distortion continues. Ordinarily, the fields change in concerted ways during the rhythmic events of eating, excreting, breathing, and sleeping.

When a state of excitement persists long enough for the cell to produce an excess of lactic acid, causing it to become more strongly charged electrically, nearby blood vessels and nerves will tend to grow into the area, restoring normal energy supply and integrated functioning. (Lactic acid can be demonstrated to stimulate vascular growth by putting it near the eye's cornea, causing blood vessels to invade previously clear areas. In cell culture, McCaig demonstrated that nerve cells grow toward the negative electrode.)

When a cell has been damaged (as by radiation or toxins), its inefficiency creates a small *localized distortion* in the fields, which will stimulate processes of repair or removal and replacement, as far as the organism's resources allow. When a stress is great enough that the *entire organism* is exposed to lactic acid, the organism's adaptive resources are being challenged, and potentially harmful responses are evoked. For example, a sluggish liver can allow the blood lactate concentration to rise during stress, and this can lead to secretion of endorphins and pituitary hormones (Elias, et al., 1997). The endorphins can increase histamine release, and growth hormone increases free fatty acids; increased permeability of blood vessels can allow proteins and fats to leave the blood stream with cumulatively harmful effects.

In general, the factors that protect against harmful local activation of cells are also protective against maladaptive general responses.

The doctrines that explain aging, cancer, and other diseases in terms of the "wearing out of cells" have been based on the denial of the role of organismic patterns and fields in the regulation of events on the cellular and molecular levels. Those theories or doctrines have been popular because they fit the "reductionist" idea of science, which tries to explain the organism as a whole in terms of its smallest parts. The investigation of regeneration, which requires thinking in terms of patterns and fields, has been retarded by that essentially antibiological culture of reductionism.

Sodium and carbon dioxide are essential for maintaining the normal fields, and these substances interact in ways that cause both of them to be lost during stress. In hypothyroidism, sodium is persistently lost, as carbon dioxide is chronically replaced by lactic acid.

Both sodium (Veech, et al.; Garrahan and Glynn) and carbon dioxide--by stimulating the Krebs cycle, and keeping the respiratory enzymes active--help to maintain the normal level of ATP, protecting against stress and shock.

The interlocking fundamental features of cell excitation/relaxation, electrical potential, lactic acid/carbon dioxide, water retention/water loss, salt regulation, pH and energy level, allow us to visualize in a coherent way the biological meaning of stress and adaptation. Interacting with those physical-chemical events, there are many layers of biochemical and physiological processes that reinforce or modify them, including regulatory systems such as hormones and other biological signaling substances, nutritional adequacy, and the type of fuel used. The safest and most effective interventions will be those which support our basic organizational fields (sodium, carbon dioxide, balanced proteins, fruits, thyroid, pregnenolone, for example), and don't introduce distortions, as some drugs, foods, hormones, and supplements do.

"**Although ventilation is greatly increased, it is a paradox that cardiac output for a given work level is the same in acclimatized subjects at high altitude as at sea level.** Stroke volume is reduced but not because of impaired myocardial contractility because this is preserved up to extreme altitudes. Indeed the normal myocardium is one of the few tissues whose function is unimpaired by the very severe hypoxia." **"In spite of the greatly reduced aerobic capacity, anaerobiosis is greatly curtailed, and it is predicted that** above 7500 m, there is no rise in blood lactate on exercise."

Stubbs M; Veech RL; Griffiths JR, "Tumor metabolism: the lessons of magnetic resonance spectroscopy," *Adv Enzyme Regul 35,* 101-15, 1995. For many years after Warburg's classic work, it was generally assumed that tumors produced large amounts of lactic acid and consequently had an acidic intracellular pHi. However, with the advent of Magnetic Resonance **Spectroscopy (MRS), a non-invasive in vivo measure of tissue pH became available and demonstrated that in both human and animal tumors, pHi was higher (> 7.0) than pH epsilon (< 6.8), in contrast to normal tissues (e.g., liver) in which pHi (approximately 7.2) is lower than pH epsilon (approximately 7.4).** This result has been confirmed in animal tumors using an MRS-visible extracellular marker, 3-aminopropyl phosphonate. The pH gradient across the tumor cell membrane is part of an interrelated system of ionic gradients and measurements made by both 31P MRS and by conventional analysis in Morris hepatoma 9618a and in livers demonstrated that the following ions also changed:

compared with liver the Na+ content was 2-fold higher, K+ was 20% lower, total Ca2+ was 8-fold higher (7.4 mumol/g wet wt) and total Pi 2-fold higher (8.5 mumol/g wet wt), suggesting the presence of insoluble calcium phosphate, **HCO3- was lower, total Mg2+ was similar in both tissues, but free [Mg2+] (calculated by two different methods) was approximately 5-fold lower in the hepatoma, as was [ATP]/[ADP][P(i)]. Because of an inadequate blood supply, tumors are often hypoxic with impaired Krebs cycle activity, low [ATP]/[ADP][P(i)] and rely mainly on glycolysis for energy. The rapid production and subsequent export of anionic lactate-from the tumor cell would be accompanied by H+.** This would account for reversal of the proton gradient and activation of the Na+/H+ exchange. The elevated [Na+]i would decrease the Na+/Ca2+ exchange, which would in turn tend to cause the accumulation of Ca2+ (and P(i)). Such calcification is a very common feature of tumor pathology. The data indicate the change in gradient of one ion (H+) involves alterations in the linked equilibria of many ions and also of energy metabolites and offers new insights into properties of tumors important both diagnostically and therapeutically.

Kayser B, "Lactate during exercise at high altitude," *Eur J Appl Physiol 74(3),* 195-205, 1996. "In acclimatized humans at high altitude the reduction, compared to acute hypoxia, of the **blood lactate concentration (la) at any absolute oxygen uptake (VO2), as well as the reduction of maximum la (lamax) after exhaustive exercise, compared to both acute hypoxia or normoxia, have been considered paradoxical**, and these phenomena have therefore become known as the 'lactate paradox'." "At present, it appears that the acclimatization-induced changes in [la-] during exercise are the result of at least two mechanisms: (1) a decrease in maximum substrate flux through **aerobic glycolysis due to the reduced VO2max** in hypoxia; and (2) alterations in the metabolic control of glycogenolysis and glycolysis at the cellular level, largely because of the changes in adrenergic drive of glycogenolysis that ensue during acclimatization, although effects of changes in peripheral oxygen transfer and the cellular redox state cannot be ruled out. With regard to the differences in lactate accumulation during exercise that have been reported to occur between lowlanders and highlanders, **both groups either being acclimatized or not,** these do not seem to be based upon fundamentally different metabolic features. Instead, they seem merely to reflect points along the same continuum of phenotypic adaptation of which the location depends on the time spent at high altitude.

Buteyko, K.P., "The theory of CO2-deficient diseases of civilisation as an adaptation to the evolution of atmosphere," Kiberneticheskie Aspekty Adaptatsii Sistemy "Chelovek-Sreda," Tez. Seminara, Moscow, 1975, seminar thesis.

Stubbs M; Rodrigues L; Howe FA; Wang J; Jeong KS; Veech RL; Griffiths JR, "Metabolic consequences of a reversed pH gradient in rat tumors," *Cancer Res 54(15), 4011-4016,* 1994. "We have previously demonstrated (M. Stubbs, Z. M. Bhujwalla, G. M. Tozer, L. M. Rodrigues, R. J. Maxwell, R. Morgan, F. A. Howe, and J. R. Griffiths, *NMR Biomed.5,* 351, 1992) that the intracellular pH (pHi) of several rat tumors is higher (> pH 7.0) than that of the tumor extracellular fluid (pHe), in contrast to normal tissues (e.g., liver) in which pHi is lower than pHe. In this paper we confirm a pHe of 6.8 +/- 0.07 (SEM) in Morris hepatoma 9618a by an independent method and report the tissue content of other ions by both 31P magnetic resonance spectroscopy and by conventional analysis in hepatomas and livers in rats. Compared with liver, tissue Na+ was 2-fold higher and tissue K+ was lower. Tissue Ca2+ was 8-fold higher (7.4 +/- 4.3 mumol/g wet weight) and tissue Pi was 2-fold higher (8.5 +/- 1.3 mumol/g wet weight) suggesting the presence of insoluble calcium phosphate. Cl- was unchanged (approximately 40 mumol/g wet weight), whereas HCO3- was lower in the hepatoma (12.4 +/- 0.83 compared to 15.5 +/- 0.76 mumol/g wet weight). Total tissue Mg2+ was similar in both tissues, but free [Mg2+] (calculated by two different methods) was approximately 5-fold lower in the hepatoma. The ATP values were 3.5-fold and [NAD]/[NADH] 9-fold lower in the hepatoma. The results are compatible with the hypothesis that the chronic partial hypoxia of tumor tissue involves changes in the linked equilibria of many ions and metabolites and may help explain such pathologies as calcification."

Erjefält I; Persson CG, "Inflammatory passage of plasma macromolecules into airway wall and lumen," *Pulm Pharmacol 2(2),* 93-102, 1989. "Anaesthetised guinea-pigs received tracer macromolecules 70-340 kDa intravenously and their erythrocytes were labelled in vivo with 99mTc." "It is suggested that the consistent inflammatory stimulus-induced passage of plasma into the lumen is a consequence of a load on the basal side of the epithelium induced by the extravasated plasma and its derived peptides. An increased

interstitial pressure may transiently separate many epithelial cells allowing a mainly uni-directional almost unrestricted flow of large solutes into the lumen."

"Decreased hemolysis during storage of blood saturated with CO2 resulted from significant changes in metabolism of erythrocytes expressed by decreased glycolysis rate....and by increasing affinity of hemoglobin for oxygen."

Notes:

[The living cell is different from most other electrically polarized materials in being able to adjust its charge, its affinity for small molecules and ions, and its shape. During stimulation (and contraction of a muscle), the phase potential may momentarily disappear as proteins' affinity for potassium, sodium, and calcium change, but the sigma potential doesn't, and may even increase slightly. The nature of the excited state is different in different environments, for example, at high altitude or in the presence of increased carbon dioxide, muscles don't contract as fully, and don't produce as much lactic acid during their maximal activity, as they do under conditions of high oxygen and low carbon dioxide pressure.]

[Increased carbon dioxide lowers the so-called membrane potential (Ling and Gerard, 1949), which I interpret as being almost equivalent to a lowering of the "injury potential." There are several more direct indications that carbon dioxide protects against destructive excitation. Muscle contraction is limited by increased carbon dioxide, and at high altitude, maximum exertion is limited, very probably because of the Haldane effect, in which carbon dioxide is retained in proportion to the oxygen deficit.

Carbon dioxide increases the association of water with proteins, a process analogous to lowering the temperature; both cold and high CO2 concentrations have a similar effect on muscle relaxation after contraction. (Howell, 1920)

A deficiency of carbon dioxide (as in hyperventilation) tends to cause epileptic seizures and muscle cramps, and is a factor in asthma and several other diseases (Buteiko) which seem to involve excessive cellular excitation. I think it acts by way of reducing the overall electrical charge of proteins, probably acting as a "cardinal adsorbant," in Gilbert Ling's sense--a molecule which, when bound to a protein, changes the protein's affinity for other molecules.]

[When a needle is poked into a cell, it obviously injures the cell, but the doctrine of the "plasma membrane" leads people to deny that what they are measuring is a type of "injury potential." They want to say that they are measuring a disequilibrium between the inside of the cell and the outside. (A disequilibrium has to be maintained by some charging mechanism such as a "pump.") They talk about the significance of the "membrane potential" as if the presence of the electrode hardly had an effect on the cell. And the surface (or sigma) potential always seems to be forgotten by these people, who think of the outside of the cell as "positive."]

Tissue Firmness and Elasticity, and Rothen's Resonance: Forgotten Physics and Aging

The most interesting problems exist exactly where the professionals assert that there is no problem at all.

The space between cells is of interest to many specialists, but it is relegated to the background in mainline medical thinking. In reality, the stuff between cells is the biggest part of a complex organism, and it contains many of the answers to questions of individuality, immunity, growth, aging, healing, sickness, and regeneration.

Respiration is essential for the existence of higher organisms, making it possible to maintain complex and adaptive structures, containing appropriately differentiated cells. I want to introduce some ideas about how respiration is involved in the creation of structures both inside cells and in the spaces between cells.

The idea of "containment in the cell" has directed attention away from the ways in which a cell knows what it is and where it is, and where it should be, what it should do.

The material in between cells has been dismissed as little more than glue, but it is where some of our most important things happen.

But first, I want to outline some of the mental habits and fixations that have been retarding biology and medicine for a long time, keeping people from thinking about these organismic issues.

THE BIAS AGAINST SENSITIVITY

In dead vegetable matter, "cells" were the empty spaces in the fibrous framework. Plants could be grafted or propagated from cuttings, making it clear that one type of plant tissue could generate the other types. The "essence" of plants was considered to be little more than growth, and their seeds had the disadvantage of introducing individual variation. Grafting and cloning animals didn't seem to work, and the idea grew up that the animal's essence was contained in the germ cell, while the plant's essence was in its vegetation.

"Contained" in the "cell," our "essence" had only to reveal itself. A man's semen was his essence, which introduced the soul into the egg, animating it. Replacing "preformationism" with "epigenesis" simply introduced the idea of individualism, by saying that a new individual came into existence by fertilization, but it didn't

Carbonated water is such a common thing, chemists are embarrassed to talk about it.

All the water in respiring organisms contains a considerable amount of carbon dioxide.

Carbon dioxide binds to proteins and to other amine-containing polymers, and dissolves in water, reducing the pH, so that the interactions of polymers and water are strongly affected by the concentration of CO2.

Carbon dioxide modifies biological materials and structures in and around our cells.

end the belief that our identity was "contained" "genetically" *within the cell.*

The neat little compartments seen in plant tissues became a sort of mental armature that no one questioned. Almost all of biology has been reduced to the idea that "the necessary information is *contained within* the cell, in its genes." The "Central Dogma" of molecular biology was stated as "information flows from DNA to RNA and from RNA to protein, and not the other way." To speak of cellular sensitivity (as Lamarck did) is to assert that information flows *into* cells; the fanatical opposition to Lamarck that has characterized biology in the 20th century has blended into a general hatred of "vitalism," the idea that life could be explained in terms of its special, living qualities. **The dogmatists insist that life must be explained in terms of physics as they understand it, and it happens that their "physics" is nothing but a doctrinal relic kept in place to justify their conceptions of biology.**

The idea that cells are governed by their responses to whatever surrounds them has taken a long time to develop, and the dogmatists still feel that there is something impermissibly "vitalistic" in the idea that cells are sensitive or responsive. To be sensitive is to receive information from "outside," and so the anti-Lamarckian ideas of evolution and adaptation were extended into the fields of development, immunity, aging, even learning. "Clonal selection" has been proposed to explain everything that happens in the organism, from development to cancer, because this view is compatible with the doctrine that information flows only from the genes to the cell; the cells simply die if they don't contain the necessary information. "Programmed cell death," in which a genetic code--a program, like a computer program--specifies the time at which a cell will die, is a characteristic part of this doctrine about the nature of a complex organism.

I think it is necessary to look at these established ideas, which are absurd and unfounded, because we are forced to wallow in them every day, until people have come to treat them as if they were intelligent, intellectually responsible, descriptions of reality; if we realize that silly ideas and connotations have been built into our language, then we can begin to give serious attention to the "anomalies" of science.

"Anomalies" are facts that don't obey the law, and so they are of special importance for anyone who cares about understanding things. If you have some parts left over after you have assembled a puzzle, maybe the puzzle wasn't correctly assembled. So-called anomalies are often the most productive places to look for solutions.

CELLULAR JUDGMENTS

That cells may be small or large or giant hasn't seemed problematic to most biologists. The assumption seems to have been that they "are big enough to contain their essential genes."

Once or twice, I have got biologists to talk about the question of how a cell knows that it is big enough to divide. I think the essence of their answer is something like "they count the molecules," which is to embarrassingly compound the puzzle, like the farmer who explained his marvelous ability to rapidly count the cows in a field by saying that he "simply counted the teats and divided by four."

The same kind of question can be applied to the thickness of layers of extracellular material, such as the basal lamina of capillaries. For example, granted that a cell should rest on a structure of a certain uniform thickness, how does a cell know when to stop secreting the material? When it is modifying the chemical composition of its extracellular matrix, how does it determine that the right composition has been achieved, when the substance is outside the cell?

Cells have to, in some sense, perceive themselves and their environment, because their environment is an essential part of their existence, governing what they are and what they can become. To understand the nature of cellular perception, we have to look beyond existing descriptions of what cells are.

In plants, the fibrous, cellulose-based walls between cells don't prevent all interactions between cells, but they do keep the cells from wandering, and they act as stable regulators of the cells' functions. Animal cells also have a carbohydrate-rich layer surrounding them, which

powerfully regulates their functions, but this layer is much more adjustable than the cellulose framework of plants.

The chemical and structural plasticity of this intercellular material is an essential part of the greater sensitivity and complexity of animals, and while it is now conventional to describe this material as part of a signalling and regulatory system, I think it might also be appropriate to think of it as **part of the cell's sensory system.** It forms a buffer zone around a cell that is strongly conditioned by the cell's own activity, and when this zone is altered by the presence of another cell, or when its composition changes because of injury or infection, the influence from that buffer zone has to change processes in the cell. **For example, if we compare these layers to a film of soap around a drop of oil, the surface tension--and therefore the shape--can change radically under the influence of physical and chemical agents, such as temperature, salts or acids.**

The forces inside cells that contribute to their shape, interact with external forces and with internal and external chemical reactions. The composition of the extracellular matrix is now known to have a profound regulatory influence on the cell's genes. The cell's "phenotype" (our phenotype is what we appear to be) is regulated by the extracellular matrix, in combination with a variety of hormonal, nutritional, and metabolic factors.

A DIFFERENT PHYSICS

In the study of cohesion, adsorption, radiation, diffraction, and resonance, there has been a strong tendency to avoid questions of the "ensemble," in favor of the unique, or at most double, event or situation--one or two atoms or molecules, one or two frequencies--and beyond that, to describe things with "statistical, stochastic, colligative" assumptions and methods. Crystallography is an attempt to understand ensembles of atoms or molecules, but it represents the opposite extreme of abstraction, letting geometry replace concrete data about events in time and place. What has always been left out is the way in which long range order interacts with local, and delocalized, energy. There have been observations with relevance to these issues, but they have been "left out" because they were "anomalous."

These interactions of the parts of an ensemble over distances many times greater than the size of an atom are of special importance for biology; they are where we find all the most interesting questions in biology.

The way the various "anomalies" fit together is a matter for a general revision of science, but in biology, **the work of Alexander Rothen gives us a tool for beginning to make sense of some of the realities of biology that have seldom been thought about.**

When I began studying biology at the University of Oregon, the bulletin board near the electron microscope room displayed some photographs of crystals that professor Bajer had been making. One of them showed a quartz crystal, over which a thin film of plastic had been coated. On top of the plastic film sodium atoms had been deposited, showing that they were being aligned in a pattern conforming to that of the underlying quartz crystal. The film was much thicker than the units of silicon dioxide in the underlying crystal, so the arrangement of the sodium atoms was obviously not being determined by either the position of the plastic polymer molecules, or the relatively remote individual silicon and oxygen atoms below the film, but somehow by a projection of the pattern of the quartz crystal. Order had been projected through the disordered layer of polymer.

Earlier, I had read some of Michael Polanyi's work with long-range effects in crystals, and knew about his adsorption work, in which the adsorptive force of the underlying charcoal was able to make itself felt through several layers of atoms, continuing to cause more atoms to condense from the gas phase. Later, multilayer adsorption was explained as the result of electronic resonance.

Rothen, using the techniques he had invented for measuring the thickness of extremely thin films, found that metal-plated glass slides, coated with albumin, would bind multiple layers of antibodies which were specific for the albumin. Or, before the slide was exposed to antibodies, it could be coated with a plastic (Formvar) film 120 Angstrom units thick, and still, **layers of**

antibodies up to 80 Angstroms thick could be adsorbed.

Polanyi's multilayer adsorption was considered impossible by the leading physicists of the time, but the simple idea of electronic resonance eventually made it possible for them to accept the facts. But Rothen's adsorption of multilayers of immunologically specific proteins was just too much.

A couple of years after I had seen Bajer's micrographs, I asked him about them, and he said he didn't remember; **already, the opinion makers in science had reacted to experiments in which cells appeared to be "feeling" an artificially constructed gradient through a plastic film, by claiming that photographs had revealed tiny holes in the films, and the cells had been reaching through the holes and feeling the gradient directly. The cheating cells (like mind-readers who peek through their blindfolds) had been "exposed," and all the long-range transmembrane phenomena had fallen into disrepute.**

Even if the cells were "cheating" by reaching through holes in the film, the fact that they could sense the direction of the gradient, and move consistently "up the gradient," was never challenged, and it wasn't explained how reaching through the plastic could allow them to evaluate the gradient on the basis of a few samples--that in itself might require a more complicated explanation than the original idea, sensing the gradient through a film, required. The meaning of this episode is that the most influential scientists will seize even an irrelevant criticism as an excuse for ridiculing ideas that violate their dogma.

But pores in plastic films, that cells might poke their fingers through, had no conceivable relevance to Rothen's work (nor to Bajer's). **Rothen's technique could measure the thickness of the layers of antibodies, and show that they were continuous layers, several antibodies thick.** Antibodies to albumin aren't supposed to bind to themselves. The technique was so simple that a physicist visited Rothen's lab, learned his technique, and then claimed to have invented it as a method for simplifying immunological testing. **But he wanted only the commercial value of Rothen's discovery, and ignored its essential importance.**

Rothen's specific long-range adsorption, like Polanyi's earlier work, simply couldn't be responded to in a rational way. A rational response might have been to reason this way: If the organization of the underlying material projects itself strongly into the environment, then patterns in the environment must also make themselves felt in the underlying material. The same mechanism would amount to an action and a perception.

There were fields such as metallurgy, in which long-range forces, and the effects of surfaces on crystal structure, were "normal science," but in biology, physics had been reduced to the ideas that were dominant in 1915.

The conformation of a large molecule is part of its biological or immunological specificity. The specificity of conformation of any molecule must participate in the specific nature of the ensemble, and that of the ensemble, in the individual molecule. For example, certain enzyme molecules are known to arrange themselves one way in the cytoplasm, and another, random way when they are examined in the unnatural environment of biochemist's test-tube.

Since Polanyi's multilayer adsorption was explained as a resonance phenomenon, the same term could be applied to Rothen's specific adsorption, without implying that we understand exactly how it works.

Rothen also showed that enzymes can act across the films. To me, the main importance of this would be to highlight the extent to which an archaic physical view has governed biochemical thinking. The action of an enzyme at a distance means that its catalytic region might be larger than previously supposed, but it also suggests that we can't generalize from the behavior of an enzyme dissolved in water, to its behavior in the cell, where it would be subject to the reciprocal effects of many other components of the complex system. Biochemists have claimed that "biochemistry couldn't exist if you doubted that the function of enzymes in solution is identical to the function of enzymes in the cell," but other

biochemists have demonstrated that **some of the most basic assumptions of biochemistry were mistaken (Bernhard, 1988), including the assumption that the enzymes of glycolysis act on substrates that are floating around in solution.**

Digestive enzymes, added to a solution containing the food materials normally digested in the intestine by those enzymes, failed to alter the food materials at a rate that could be compared to that of normal digestion. But when a formalehyde-fixed piece of intestine was added to the mixture, the reactions occurred at approximately the rate that is normal for digestion. Although in young infants digestion does happen in the fluid contents of the intestine, after the age of one, most of the action of the digestive enzymes occurs at or near the surface of the intestine, under the influence of the adsorbed enzymes. This is another clear example of the idea that enzymes are dependent on their environment.

Whether or not cells are able to "feel" what is beneath a plastic film, recent evidence indicates that the thickness and composition of the material they sit on does make a difference. Their genes are turned on by the structures that are sensed in the extracellular matrix, and the longevity, growth, function and death of the cells are determined by the nature of the substances outside the cell.

The implication of much current research is that if all of the specific protein filaments can be identified that form links between the structural filaments inside cells and the matrix materials outside the cells, the powerful influence of the external matrix on the cells' functions will somehow be explained without having to think in terms of physical ensembles. **"This protein on one side of the [imaginary] cell membrane tugs on a protein on the other side," and then maybe the little homunculus who counts molecules will decide the time is right for him to carry a message to the correct gene to turn it on.**

It is probably true that a general picture can be completed after all of the details are present, but it isn't necessarily true that the specific interpretation will be meaningful. But at the present, we can see some of the meanings of the interaction between matrix and cell.

MUCUS, MUCINS, AND MYOPIA

The importance of carbon dioxide for respiration has been established, and its essentiality for even single-celled organisms has been reported. Whenever there is respiration, carbon dioxide is produced. By maintaining the effective concentration of Krebs cycle material, it protects the efficiency of respiration. Carbon dioxide is very soluble in water, but it is even more soluble in living tissue, so soluble that it will move from a low concentration in bath water into the body, where its concentration is already much higher.

Its high concentration in bone is not usually appreciated, but calcium carbonate is the form in which calcium is first deposited in new bone. Carbon dioxide reacts spontaneously with ammonia, and with other amines. The reaction of ammonia with carbon dioxide is the first step in the formation of urea, protecting against the potential toxicity of ammonia. Proteins probably bind a little more carbon dioxide on their amino groups than the amount that dissolves in a similar quantity of water, but biologists generally talk only about the carbamino content of hemoglobin, since the binding of carbon dioxide to this protein regulates the blood's ability to deliver oxygen to the tissues.

Carbon dioxide strongly influences the way in which water interacts with proteins, and it participates in the ability of iron-binding molecules to carry iron.

Although carbon dioxide probably associates with most of the amino groups in the body, only a few of these reactions have been studied. For example, it is known to bind to insulin, affecting its conformation. I think this is likely to explain some of the effects of the thyroid hormone in diabetes, since thyroid increases the production of carbon dioxide.

Mucins, or mucopolysaccharides, are combinations of proteins and polysaccharides, which make up a large part of the extracellular matrix; the blood–type substances are mucopolysaccharides, as are chondroitin and hyaluronic acid. The

carbohydrate chains of the mucins are made up of alternating sugars and amino sugars. When the amino groups are free, they will tend to associate with carbon dioxide, and so the way they interact with water, with each other, and with proteins, will be modified according to the amount of carbon dioxide present.

The simplest way to visualize the effect of carbon dioxide on mucopolysaccharides is to think of its action as an expectorant, in which it decreases the viscosity of bronchial mucus, allowing it to be reabsorbed or expelled. Since iodide also has a long history of use as an expectorant, we should compare the effects of carbon dioxide and carbonic acid with the effects of iodide in other situations.

The transparent structures of the eye are interesting places for considering the effects of carbon dioxide. I think carbon dioxide has a role in maintaining the clarity of the lens, as I discussed in the cataracts newsletter, **by preventing swelling**. The connective tissues of the eye's sclera and cornea are rich in mucopolysaccharides, and the vitreous body and the aqueous humor are very much like more dilute solutions of the same materials--the cornea is the most dense, and the aqueous is the most dilute. The fluidity of the aqueous is important because it circulates nutrients and oxygen from the blood, to sustain the lens and the cornea. The individual molecules in the aqueous are larger than those in the vitreous, but because there are fewer of them, the aqueous isn't very viscous. If carbon dioxide affects these molecules as it does the mucins in the bronchial secretions, then we can infer that it is important in maintaining the fluidity of the aqueous humor; **this would suggest that hypothyroidism, leading to a substitution of lactic acid for carbon dioxide, might contribute to the development of glaucoma by increasing the viscosity of the aqueous humor.**

Among mountain climbers, it has been reported that after staying several hours at a very high altitude, there is a decrease in the degree of myopia. Because of the Haldane-Bohr effect, in which carbon dioxide is retained when less oxygen is available, I think the high altitude effect on myopia involves a condensation of the connective tissue. In experimenters wearing gas tight goggles, and in scraped corneas kept in tissue culture, carbon dioxide has been found to have an **anti-swelling effect on the cornea.**

When rats have their thyroid glands removed, they become nearsighted, but if their pituitary glands are removed at the same time, they don't develop myopia. Hypothyroidism is classically associated with "myxedema," in which the tissues become overloaded with the glycoproteins or mucins. Several pituitary hormones are known to stimulate the overproduction of mucins.

In several of my classes, I asked students if they remembered when they became nearsighted. Although puberty is the usual time for myopia to begin, several girls mentioned that they had needed glasses within a month of beginning the oral contraceptive pill, and some of them found that their vision returned to normal when they stopped the pill, or began using thyroid supplements. High prolactin (associated with high estrogen or low thyroid) may be one of the factors in myopia.

Another experimental method for producing myopia is to cover the eye of a growing animal, or to keep the animal in constant darkness. In darkness, the eye grows larger than normal, causing the refractive error of myopia, and the sclera is soft and weak. Since stimulated nerves consume oxygen and emit carbon dioxide, I think darkness might mimic hypothyroidism, allowing the connective tissues to swell.

The sea cucumber has been used to study the physical properties of connective tissue, and it has been found that certain salts tend to soften the connective tissues, but that iodide doesn't. The well-established use of iodide to resolve granulomas, even when it doesn't eliminate the infectious agent, might suggest that it is protecting against something which is disrupting the connective tissue structure.

The only publications I have seen that presented clear evidence of the disappearance of arteriosclerosis involved treatment with iodides. In the retina, blood vessels can be seen to return to their normal appearance following a course of iodide treatment. Besides its possible direct effects on the mucins, iodide might help to

eliminate calcium from the walls of blood vessels, since calcium iodide is very soluble.

In aging, connective tissue becomes hardened by chemical cross-linking of the large molecules. If amino groups are well saturated with carbon dioxide, this type of reaction should be inhibited. (Carbon dioxide also inhibits the production of free radicals, which are involved in some types of cross-linking reactions.) The waterlogged condition seen during shock or stress in blood vessels, lungs, and other organs, and the edema of the brain and cataracts of the lenses that follow metabolic impairments of various sorts, seem to involve the uptake of "free" water, at the same time that "bound" (unfreezable) water is lost. Carbon dioxide seems to promote the retention of bound water, and protects against the edematous conditions. The swelling of muscles during hypoxic stress probably represents the basic process, in which lactic acid and pH increase, while CO_2 is lost.

Whatever the cell's "membrane" structure may be, Rothen's demonstration of the deep interactions of adjacent layers showed that the conditions on either side of the surface of a cell are very sensitive to conditions on the other side.

Since the mucopolysaccharides regulate cell division, cell shape and motility, cell longevity and cell death, and carbon dioxide has very powerful structural effects on the mucopolysaccharides, the cell, by producing carbon dioxide, is stabilizing its regulatory framework, the extracellular matrix, at the same time that it stabilizes the intracellular proteins and systems of metabolism..

The thyroid hormone is the most important promoter of carbon dioxide formation.

"Daily periodicity in the activity of a slide used to perform immunologic reactions at a liquid-solid interface," Rothen A, **Proc Natl Acad Sci U S A, 1975 Jun, 72:6, 2462-4.** "Nickel-plated slides were prepared by evaporating a nickel layer (congruent to 4000 A thick) on glass slides in the presence of a magnetic field whose lines of force were perpendicular to the surface of the slides. Such slides are called active. After being coated with a layer of bovine albumin, they could absorb a layer of antibodies 70-80 A thick. However, if the active slides before they were coated with bovine serum albumin, were submitted to a magnetic field with lines of force parallel to the surface, the layer of antibodies absorbed was only 40 A thick. They had become inactive. It has been found that slides remain active at night but that shortly after sunrise they become slowly inactivated and reach a minimum in their activity at exactly the midday period. They regain full activity at sunset. It is shown that the inactivation results from a solar radiation that can be stopped by 3.5 cm of lead. On December 13th, 1974 there was an eclipse of the sun with 65% occultation at noon (Daylight Saving Time). The activity of the slide at noon was 65% of the maximum activity (83 A) observed before sunrise. The thickness of the adsorbed layer of antibodies were 75 A instead of 63 A observed in the absence of the eclipse. The activation of the slides originates in a radiation of non-solar origin that is adsorbed by 1 can of lead."

"Adsorptions of purified serum proteins on metalized glass slides and their significance for the immunoelectroadsorption method," Mathot C, Rothen A, **J Colloid Interface Sci, 1969 Sep, 31:1, 51-60.** "Tryptic action across a membrane. Rothen A, Physiol Chem Phys, 1979, 11:6, 481-9. Tryptic action occurs when a layer of bovine serum albumin adsorbed on a nickel-plated slide and protected by a Formvar membrane 120 A thick is treated with dilute trypsin solution. But experimental evidence indicates that the trypsin molecules do not cross the membrane. Thus the proposal that trypsin can exert its enzymatic action without intimate contact with the substrate, first **set forth in 1948 but later abandoned in favor of a "forced diffusion" hypothesis,** now appears the correct interpretation. Analogously, antibodies can be specifically immobilized on one side of a membrane separating them from adsorbed antigens located on the other side."

Y.Mitsui, et al., "Cell surface changes in senescent and Werner's syndrome fibroblasts: Their role in cell proliferation," Adv. Exp. Med. Biol. 190, 567-585, 1985. "Cell surface is known to participate in the regulation of cell proliferation through interaction with adjacent cell surfaces or the extracellular matrix, or both." "We here examined, in vitro and in vivo, alterations of the cell-surface properties of Werner's syndrom cells and aging human fibroblasts. Cell-surface negative charges, examined by electrophoretic mobility of dispersed single cells in buffer, were seen to decline steadily as a function of cumulative population doublings." "...the cell-surface negative charges were

attributable to sialic acid, chondroitin sulphates, hyaluronic acid, and heparan sulphate." "Cell growth was inhibited 40% when the fibroblasts were cultured on the fixed sheets of late passage cells. Treatment of the fixed cell sheets with heparitinase or nitrous acid resulted in complete recomvery from the growth inhibition. Cell growth on sheets of fixed cells derived from young, middle, and senescent fibroblasts showed that the surface of the senescent cells had the greatest inhibitory effect. These inhibitory effects of fixed cell sheets correlated well with both the amount of heparan sulphate relative to the total GAGs on the surface and to the saturation density of cell crowth at each passage. These findings strongly suggest that heparan sulphate, or its complex, on the cell surface in involved in the regulation of cell proliferation."

"The intracellular equilibrium thermodynamic and steady-state concentrations of metabolites," Bernhard SA, Institute of Molecular Biology, University of Oregon, Eugene 97403. Cell Biophys, 1988 Jan-Jun, 12:, 119-32 "A new model for the organization and flow of metabolites through a metabolic pathway is presented. The model is based on four major findings. (1) The intracellular concentrations of enzyme sites exceed the concentrations of intermediary metabolites that bind specifically to these sites. (2) The concentration of the excessive enzyme sites in the cell is sufficiently high so that nearly all the cellular intermediary metabolites are enzyme-bound. (3) Enzyme conformations are perturbed by the interactions with substrates and products; the conformations of enzyme-substrate and enzyme-product complexes are different. (4) Two enzymes, catalyzing reactions that are sequential in a metabolic pathway, transfer the common metabolite back and forth via an enzyme-enzyme complex without the intervention of the solvent environment. The model proposes that the enzyme-enzyme recognition is ligand-induced. Conversion of E2S and E2P results in the loss of recognition of E2 by E1 and the concomitant recognition of E2 by E3. This model substantially alters existent views of the bioenergetics and the kinetics of intracellular metabolism. The rates of direct transfer of metabolite from enzyme to enzyme are comparable to the rates of interconversion between substrate and product within an individual enzyme. Consequently, intermediary metabolites are nearly equipartitioned among their high-affinity enzyme sites within a metabolic pathway. Metabolic flux involves the direct transfer of metabolite from enzyme to enzyme via a set of low and nearly equal energy barriers."

Cytoarchitecture and cell growth control. Slack JK; Higgins PJ Cell Motil Cytoskeleton, 1996, 33:2, 83-7 Appropriate cell-to-substrate adhesion together with SGF stimulation is **necessary to initiate and continue cell cycle progression of growth arrested cells. Adhesion-dependent signaling events, which likely occur through integrin receptors specifically organized with cytoskeletal components within focal contacts, can induce expression of specific genes and stimulate quiescent cells into the growth cycle.** The mechanisms as to **how:** (1) cell-to-substrate adhesion complexes are formed and maintained, (2) adhesion-dependent signal transduction events interface with SGF initiated signalling events, (3) adhesion influences expression of growth-state regulated genes, and (4) an appropriate **cytoarchitectural environment may coordinate these events to regulate cellular growth are unclear.** While it is apparent that defining these mechanisms would be critical to understanding the basic events which control cell growth, many of the mechanisms are just beginning to be addressed and understood."

"Three-dimensional analysis of the substrate-dependent invasive behavior of a human lung tumor cell line with a confocal laser scanning microscope," Strohmaier AR; Spring H; Spiess E Biomedizinische Strukturforschung (0195), Deutsches Krebsforschungszentrum, Heidelberg, Germany. Histochem Cell Biol, 1996 Mar, 105:3, 179-85 Matrigel and collagen G gels were used as models for basement membrane and interstitial space-collagen, respectively, to study the invasive behavior of cells of the human lung tumor cell line EPLC 32M1, which was derived from a squamous cell carcinoma. For three dimensional analysis of the invasive process, cells were seeded onto the gels in a slide chamber and observed with a confocal laser scanning microscope. Optical sectioning in the xy and xz directions and image reconstruction with computer programs allowed us readily to obtain a three-dimensional overview of the invasive process in situ. Both types of gel showed a smooth surface. Matrigel had a granular structure whereas collagen G revealed a fiber-like morphology. The tumor cells showed a matrix-dependent behavior. On Matrigel, within 24 h of incubation, a network of cells appeared on the surface, which developed further within 72 h to interconnected multicellular cords also invading the gel. Tumor cells seeded on collagen G remained individual. They formed pseudopodia and achieved tight contact with the matrix, eventually also invading the gels in a time-dependent manner. **Therefore, the composition of the substrate crucially influences the invasion path,"**

"Modulation of protein tyrosine phosphorylation by the extracellular matrix," Corbett SA; Schwarzbauer JE J Surg Res, 1997 Apr, 69:1, 220-5 Fibronectin (FN) cross-linked to fibrin following injury provides the provisional matrix required for cells to begin tissue repair. Our previous work has demonstrated that fibroblasts adherent to multimeric FN within the context of a fibrin matrix (FN-fibrin) **exhibit clear phenotypic differences from those adherent to a dimeric FN-coated surface.** We hypothesize that this response to multimeric FN may be mediated by altered protein tyrosine phosphatase activity following integrin activation. Methods: NIH 3T3 cells were plated in the presence or absence of pervanadate (PV), a phosphotyrosine phosphatase inhibitor, on wells coated with FN or FN-fibrin matrix. Spread cell areas were measured after increasing incubation times and are recorded as mean cell area (mm2) +/- SEM. Alternatively, cells were lysed and equal amounts of protein were analyzed by immunoblot using a monoclonal antibody

specific for phosphotyrosine. Results: PV significantly inhibited cell spreading on FN-fibrin matrices. In contrast, PV treatment had little effect on cell area on FN alone. Analysis of cell lysates revealed that protein tyrosine **phosphorylation events differ in a substrate-dependent manner**. Conclusion: **Cell attachment to a FN-fibrin matrix induces distinct cell shape and cytoskeletal organization.** Inactivation of tyrosine-specific phosphatases enhances this distinction and inhibits the spreading of cells attached to this substrate. The phosphotyrosyl protein content of treated cells on FN-fibrin matrix is also diminished. These results suggest that **cell-extracellular matrix interactions affect the tyrosine phosphorylation balance of the cell, thus modifying cytoskeletal organization** and related signaling events."

"Inhibition of anchorage-dependent cell spreading triggers apoptosis in cultured human endothelial cells," Re F; Zanetti A; Sironi M; Polentarutti N; Lanfrancone L; Dejana E; Colotta F Borgomainerio, Milano, Italy. J Cell Biol, 1994 Oct, 127:2, 537-46 When cultivated on substrates that prevent cell adhesion (the polymer polyhydroxyethylmethacrylate, bovine serum albumin, and Teflon), human endothelial cells (EC) rapidly lost viability with a half-life of approximately 10 h. Dying EC showed the morphological and biochemical characteristics of apoptosis. The apoptotic process of suspended EC was delayed by the protein synthesis inhibitor cycloheximide. To obtain information as to the mechanism involved in the apoptosis of suspended EC, we investigated whether **adhesion to matrix proteins or integrin occupancy in EC retaining a round shape** may affect EC suicide. EC bound to **low coating concentration** of either fibronectin or vitronectin, **retaining a round shape and failing to organize actin microfilaments, underwent to rapid cell death;** by contrast, cells on **high substrate concentrations became flattened, showed actin microfilament organization,** and retained viability. Addition of saturating amounts of soluble vitronectin to suspended round-shaped EC did not reduce the process of apoptosis. Finally, when suspended EC bound Gly-Arg-Gly-Asp-Ser-coated microbeads (approximately 10 microbeads/cell), yet retaining a round shape, the apoptotic process was not affected. Oncogene-transformed EC in suspension were less susceptible to cell death and apoptosis than normal EC. Overall, these data indicate that cell attachment to matrix or integrin binding per se is not sufficient for maintaining cell viability, and that cells need to undergo some minimal degree of shape change to survive. Modulation of interaction with the extracellular matrix can, therefore, be an important target for the control of angiogenesis.

"EFFECT OF CARBON DIOXIDE ON THE THERMODYNAMIC STATE OF WATER IN COLLAGEN," JOURNAL OF FOOD SCIENCE 53(4). 1212-1215, 1988. "Thermodynamic activities of polar sites of collagen in the presence of CO2 were observed by inverse gas chromatographic techniques using water as a probe. The interactions between collagen and the water probe were evaluated by determining the specific retention volume (Vg.degree.) and partition coefficient (Kp) at 25.degree. C, 30.degree. C, and 35.degree. C. Thermodynamic parameters were determined from these data. CO2 exhibited a significant effect on the water binding of collagen as shown by increased Vg.degree. and Kp values as compared to N2- and He-treated collagen. The thermodynamic parameters of partial molar Gibb's free energy...partial molar enthalpy...and partial molar entropy**...indicated CO2 significantly increased the average energy of water binding by collagen."**

Kinetics of decreased LPS-stimulated cytokine release by macrophages exposed to CO2. West MA; Baker J; Bellingham J, J Surg Res, 1996 Jun, 63:1, 269-74. **"The mechanisms responsible for the lack of inflammation after laparoscopic surgery remain unknown. Peritoneal macrophages (M phi) incubated in carbon dioxide (CO2) but not air or helium (He), had significant, reversible inhibition of lipopolysaccharide (LPS)-stimulated tumor necrosis factor (TNF) and interleukin-1 (IL-1)** release. In these experiments the kinetics of these C02-induced alterations in cytokine secretion were examined. Murine peritoneal Mphi were stimulated with LPS for 4 hr and incubated in different test gases (95% air/5% CO2,80%CO2/20%O2,80% He/20% O2) for intervals between 0.25 and 4 hr. Time between gas incubation and LPS stimulation was varied to determine the persistence of CO2 inhibition. Parallel M phi groups received LPS stimulation 24 hr later. Supernatant TNF and IL-1 were measured by bioassay and polymerase chain reaction was used to examine cytokine mRNA. Significant reversible inhibition of TNF and IL-1 was seen with CO2, but not He or air. **Inhibition of IL-1 occurred 15 min after CO2 exposure,** was associated with decreased IL-1 mRNA, and was rapidly lost following incubation in the control atmosphere. TNF inhibition was seen despite normal levels of TNF message, required more than 30 min of CO2 exposure, and persisted after CO2 removal. **CO2 produced profound, reversible, inhibition of LPS-stimulated cytokine release by peritoneal Mphi. The transient inability to secrete inflammatory cytokines after CO2 exposure may explain the lack of systemic inflammation after laparoscopic surgery with CO2."**

"Do plasma and serum have different abilities to promote cell growth?" Gospodarowicz D; Ill CR Proc Natl Acad Sci U S A, 1980 May, 77:5, 2726-30 "The abilities of plasma and serum to support the growth of vascular smooth muscle cells maintained on uncoated tissue culture dishes or dishes coated with an extracellular matrix (ECM) have been compared. Vascular smooth muscle cells maintained on plastic dishes and exposed to plasma proliferate poorly; when exposed to serum they proliferate actively. Addition of fibroblast growth factor (FGF) incrases the growth rate of the cultures in both cases. In contrast, when vascular smooth muscle cells are maintained on an ECM, they proliferate

equally well exposed to either plasma or serum. Because the cultures had an average doubling time (15 hr) that was already at a minimum, FGF no longer had an effect on vascular smooth muscle cell proliferation." "These results raise the possibility that the lack of response of vascular smooth muscle cells, as well as that of other cell types in vitro, to plasma factors is **not an intrinsic property of the cells but is rather due to the substrate upon which the cells rest. Because cells maintained on an ECM respond to plasma factors, it is likely that the close contact of the cells with the ECM restores their sensitivity to physiological factors present in plasma."**

"Factors controlling the proliferative rate, final cell density, and life span of bovine vascular smooth muscle cells in culture," Gospodarowicz D; Hirabayashi K; Giguère L; Tauber JP J Cell Biol, 1981 Jun, 89:3, 568-78 "Low density vascular smooth muscle (VSM) cell cultures maintained on extracellular-matrix(ECM)-coated dishes and plated in the presence of either plasma or serum will proliferate actively when serum-containing medium is replaced by a synthetic medium supplemented with three factors: high density lipoprotein (HDL, 250 micrograms protein/ml); insulin (2.5 micrograms/ml) or somatomedin C (10 ng/ml); and fibroblast growth factor (FGF, 100 ng/ml) or epidermal growth factor (EGF, 50 ng/ml). The omission of any of these three factors from the synthetic medium results in a lower growth rate of the cultures, as well as in a lower final cell density once cultures reach confluence. When cells are plated in the total absence of serum, transferrin (10 micrograms/ml) is also required to induce optimal cell growth. The effects of the substrate and medium supplements on the life span of VSM cultures have also been analyzed. Cultures maintained on plastic and exposed to medium supplemented with 5% bovine serum underwent 15 generations. However, **when maintained on ECM-coated dishes the serum-fed cultures had a life span of at least 88 generations. Likewise, when cultures were maintained in a** synthetic medium supplemented with HDL and either FGF or EGF, an effect on the tissue culture life span by the substrate was observed. Cultures maintained on plastic underwent 24 generations, whereas those maintained on ECM-coated dishes could be passaged repeatedly for 58 generations. These experiments demonstrate the influence of the ECM-substrate only in promoting cell growth but also in increasing the longevity of the cultures."

"Determination of cellular shape by the extracellular matrix and its correlation with the control of cellular growth." Gospodarowicz D; Greenburg G; Birdwell CR Cancer Res, 1978 Nov, 38:11 Pt 2, 4155-71 **"Although the problem of cellular proliferation may seem at first glance to be tremendously complex, the mechanisms which control it may be extremely simple. One of the primary factors which regulates the mitogenic response of a given cell type to a given class of mitogenic agents seems to be the cellular shape.** We have found that corneal epithelial cells, for example, adopt a flattened configuration when maintained in vitro on plastic and are very sensitive to fibroblast growth factor, but not to epidermal growth factor. When maintained on collagen, on the other hand, they become tall and columnar and respond primarily to epidermal growth factor. The cellular shape is dictated in vivo by the extracellular material upon which the cells rest and in vitro by the substrate upon which the cells are maintained. The substrate itself may, in turn, induce the cells to manufacture their extracellular material and specific cell surface proteins which control the cellular shape."

"The control of mammalian cell proliferation by growth factors, basement lamina, and lipoproteins. Gospodarowicz D J Invest Dermatol, 1983 Jul, 81:1 Suppl, 40s-50s "The effect of growth factors such as fibroblast growth factor on the production of a basement lamina by cultured endothelial cells has been investigated. The ability of these cells to grow and differentiate properly correlated with their ability to produce a basement lamina. The effect of such a substrate on the growth, differentiation, and aging of cells in vitro, as well as its use for the long-term culture of either normal diploid cells or tumor cells, is reviewed.

Effect of high and low density lipoproteins on proliferation of cultured bovine vascular endothelial cells." Tauber JP; Cheng J; Gospodarowicz D J Clin Invest, 1980 Oct, 66:4, 696-708 "Bovine vascular endothelial cells maintained on dishes coated with an extracellular matrix and exposedto medium supplemented with lipoprotein-deficient serum (LPDS) require the presence of lipoprotein to proliferate optimally. High density lipoprotein (HDL) seems to be the major factor involved in the proliferation of vascular endothelial cells. This is mostly due to its lack of toxicity when added at high concentration, as well as to its nondependence on LPDS to exhibit its mitogenic properties. Therefore, HDL hysiological concentrations (1,000--1,500 microgram protein/ml) can fully replace serum. Low density lipoprotein, unlike HDL, has a biphasic effect. Although mitogenic for vascular endothelial cells when added at low concentration, once physiological concentrations are reached it becomes toxic for the cells. Moreover, and in contrast with HDL, the mitogenic effect of low density lipoprotein was found to be a function of the LPDS concentration to which cultures were exposed. The substrate upon which cultures are maintained has been found to be an important factor if a mitogenic effect of HDL is to be observed. When maintained on plastic, cells proliferate poorly in response to HDL unless fibroblast growth factor is added to the medium. **In contrast, when maintained on extracellular matrix, an optimal growth rate is induced by HDL, even in the absence of fibroblast growth factor.** This **suggests that, in vivo, the integrity of the basement membrane upon which endothelial cells rest and migrate is an important factor in determining the cells response to lipoproteins present in plasma. "**

Le stress ultime c'est le Shock. Pour pas mourir il faut ↑ energie

Recharging the System

Adelle Davis wrote about the importance of increased salt intake in adrenal failure, and animal experimenters have demonstrated that with adequate sodium and sugar, animals can function normally without their adrenals. Hans Selye demonstrated that progesterone supplements keep animals healthy for their entire life after their adrenals have been removed. Among its many effects, progesterone regulates the levels of sodium and glucose.

Progesterone is both an antistress hormone and an antishock hormone; shock is the state that occurs when our defenses are down, and stress is just a little higher on the scale of resistance, and neither will occur when our resources are adequate. In any bad biological situation, estrogen is likely to accumulate, interfering with energy production, causing blood to pool in the legs, causing water retention and sodium loss.

> "The essence" of shock "seems to be a relative disappearance of blood from the heart and great vessels, so that the heart has not sufficient fluid on which to contract. Much used to be written about 'the mystery of the lost blood.'" W. Boyd, A Text-Book of Pathology, 1943.

Thyroid, progesterone, protein, and salt are powerful defenses against all sorts of stress-associated symptoms, including hot flashes, insomnia, cramps, PMS, edema, toxemia of pregnancy, low-birth-weight babies, epilepsy, heart diseases, hypertension, strokes, migraine, inflammatory diseases, hypoglycemia, fatigue and depression. The first approach to an appropriate diet would be to use **at least** a quart of milk and a quart of orange juice daily, well salted chicken broth, and frequent snacks, especially salty foods. I have written before about the importance of fruit and protein in balancing the hormones, and how adequate energy prevents stress, but I haven't talked about sodium's central biological role in sustaining our energy, and the mechanisms behind these effects of diet and hormones..

Shock is the most extreme stress-state there is, and it can shift gradually into death, as energy production ceases. Things that can bring an individual out of shock are so intimately connected with our energy production that we should understand how to use them routinely.

In shock, G. W. Crile showed that many systems, ranging from the molecular level to the nervous level, are involved, and he introduced methods of anesthesia that reduced shock. He imagined the organism--and each cell--as something like an electrical battery: The liver and the brain formed the poles of the organism-battery, and the nucleus and cytoplasm formed the cell's "poles." Exhaustion and shock, he believed, in some way "discharged" the organism's energy, causing changes in every cell.

> "The use of CO2 for synthetic purposes by the mammalian cell is now being studied in detail; it has already taken on tremendous significance since it completely reverses the hitherto firmly accepted view that CO2 is merely a waste product of animal metabolism. R. Levine, "Carbohydrate Metabolism," in Diseases of Metabolism, G.G. Duncan, ed., 1964.

I suspect that Crile's work on the physiology of excitement, exhaustion, and shock made Hans Selye's work on stress and adaptation "less unacceptable" to the scientific establishment than it

Shock state = Humain ne plus ↓ défense
+ Huit + Fruit + Pros + Sel Protège contre le stress

Poor trauter he shock ; Sodium, Glucose, ATP injectable, cortego & morphine Naloxone

would have been without Crile's disturbing precedent. Crile warned about the shock-promoting action of morphine, and influenced the way surgery was done, but unfortunately shock is still too often thought of in a mechanical way, as something that happens to the circulatory system, and the various subsequent discoveries about treating shock have seemed too mysterious or too implausible to gain general acceptance. In the absence of a unifying picture of the organism, treatments are likely to be evaluated in terms of a fragmented aspect of the organism, and if they don't mechanically fit into that system in an obvious way, they are dismissed.

I have written previously about several dramatically effective treatments for shock that were developed in the last fifty years--for example, intravenous ATP, concentrated solutions of sodium chloride or glucose, and the morphine/endorphin-blocker, naloxone. Theoretical reasons have kept some of these techniques from being used as widely as would be appropriate, but gradually the success of the methods is forcing some people to rethink their theories.

A simple newer view of the organism's energy is being developed, and early acceptance of this new view will make it possible to approach treatment in a way that is both integrated and specific.

Although Crile and Selye were famous for their studies of the acute effects of noxious conditions, both were interested in the long-term, cumulative effects. Crile was more explicit about the general evolutionary implications of his discoveries.

One of the least scientific aspects of conventional "evolutionary thinking" is the thought that if an organism has or does something, that thing or behavior must have "survival value." People apply evolutionary explanations in a carefree way, feeling that an explanation without factual support is better than leaving something unexplained.

Shock, inflammation, aging and death have been proposed to "have survival value," because of this totalitarian view of genetics. Couldn't it be that organisms simply aren't perfect, and that some things are just systematically screwed up? That is, an organism has a certain strength, resistance, or adaptive capacity, but if it finds itself in conditions that are too difficult, then processes that never did anything to aid survival might develop, as several individually valid defensive maneuvers start to interfere with each other. "Advance" and "retreat," eat and expel, for example, are processes that have to be functionally separated; if coordination is lost, new but confused processes will emerge. On the cellular level, excitotoxicity is an example of the loss of coordination.

In 1950 Selye, and in 1953, Rees, pointed out the similarities of estrogen's effects to the physiology of stress and shock. Hundreds of studies have confirmed the details of estrogen's actions on the circulatory system, respiration, and metabolism. Since we have the genes needed for making estrogen, it might seem that there is reason to argue that shock "has a genetic basis," but the mistake occurs when that phraseology is extended to claim that "genes for (something which produces) shock prove that shock has survival value." Estrogen's survival value exists only in the context of a whole organism with multiple ways for limiting estrogen's destabilizing actions. Estrogen's harmful effects occur when our systems for opposing it fail.

Recently, there has been a dispute about the reason for the evolution of menstruation among primates. The argument began when Margie Profet proposed that it is an anti-infective defense mechanism, a "cleansing" procedure. Culturally, this strikes me as primarily a reaction against the archaic doctrine of the "unclean" menses, and scientifically, it is hard to imagine that opening blood vessels and bathing the membranes in blood would be an anti-infective strategy; in fact, infections such as gonorrhea and chlamydia are more likely to occur after menstruation, and blood is an exceedingly good growth medium for germs. Her

> Cramps, insomnia, shock, heart attacks, and many other problems could be seen as consequences of a general energy problem, if it weren't for a few dogmatically fixed ideas that are held in place by academic/bureaucratic defensiveness and arrogance. "Membranes" and "membrane pumps" are more important than (other people's) life to these dogmatists.

response to that observation was that the prevalence of diseases such as AIDS, cholera, and tuberculosis "doesn't mean that the immune system didn't evolve to fight pathogens." I think she is wrong on both issues, the reason for evolving menstruation and the reason for evolving our immune system.*

If we can see menstruation as a side effect of the adaptations we have for producing large brains, without its own special "menstruation genes," we should also be able to see a phenomenon such as shock as something which is not biologically so useful that we "evolved" it in the sense of selecting for "shock genes." (Stumbling is a consequence of walking, and the biological point of interest is the walking, not the stumbling; any interest that stumbling has, is as a "boundary" of the ability to walk.)

My point is to suggest that shock is simply a negative thing, a failure of protective systems, a biological screw-up resulting from the same sort of inadequacy of resources that produces "excitotoxicity." *The fact that shock-like features can be seen in the hormonal effects of estrogen, and in the "normal" process of aging, leads to the thought that the body which can control the effects of estrogen should also be able to control the shock reaction and the aging process, if given the appropriate kinds of support.* Estrogen creates a bias toward cellular "excitotoxicity," since it promotes excitation while limiting energy production. Our body controls estrogen's effects by decreasing excitation while increasing efficient energy production.

The several effective methods of preventing death from shock can give us insight into this general process of the failure of life, and so into the nature of life itself.

The average biology professor is just about as unsophisticated as the average television-viewer about water in organisms--how it got there, why it stays there, what it does. The typical biologist maintains the conventional view of the cell by changing the subject whenever a fact conflicts with a doctrine. The history of the "cell membrane" shows how this mental process has worked.

At first, an oily coat was thought to account for the different composition of the watery solutions around cells, and inside cells. Then "membrane pumps" were introduced to explain the differences, because too many facts were inconsistent with the simple membrane idea. Proteins were found and identified as the pumps. Then it turned out that pumps would require energy that cells couldn't (and needn't) provide, and many ways were devised to explain the minimal energy needed to maintain the composition of cell water. But the "pump-proteins"--calcium-ATP-ase, sodium/potassium ATPase, etc.—are proteins that really exist, though their functions are much more interesting than "pumping." An important context for thinking about these ATPases is that the contractile protein of muscle (myosin) is a calcium-dependent ATPase.

The habit of biochemists has been to think of enzymes as the soluble proteins that could be extracted from cells in a watery solution, and to ignore the insoluble residue, which contained the ATPases. Now, much of the residue has been resurrected for biochemistry, under the name of "membrane proteins." The "ghost" of the red blood cell, after it has been shocked into losing its hemoglobin, is a popular lab preparation that biochemists like to call a "membrane," though the term is grossly misleading. Szent-Gyorgyi, Gilbert Ling, and a few physically conscious biologists spoke of these relatively insoluble proteins as structural proteins.

In 1968 or '69, I had been reading the previous 50 years of research on cell physiology, and I saw that for 20 years, Gilbert Ling had been almost alone in offering a view of the cell that was physically possible. He had solved the problems of ionic regulation in ways that physical chemists could accept, but biologists were proceeding as if his solutions to their problems didn't exist. I wrote to him, to see if I, as a newcomer to "science," was missing something. He said that I just didn't understand what "science" was; it was a matter of money, prestige, and influence, with little concern for what was true.

It has been calculated that the substances which are distributed unequally between cells and

the surrounding fluid would require 15 times as much energy as the cells can produce, if their distribution had to be maintained by pumps, but it has also been demonstrated that cells can remain almost at equilibrium, when their energy production is completely blocked by poisons. **Something maintains the ions and other solutes in their unequal distribution between the inside and outside of the cell, but it doesn't take energy to do it. This is why cells have been compared to ion-exchange resins, which also have the ability to passively select certain ions while excluding others.** People who have examined the atom-by-atom physics of how an ion-pump might work have demonstrated the silliness of the idea. Ion-exchange granules selectively bind certain ions that reach them by passive diffusion, and similar near-equilibrium processes can account for the ion gradients maintained by cells. The interesting difference in cells (compared to ion-exchange resins) is that their physical near-equilibrium is closely balanced with chemical processes, which are also much closer to equilibrium than conventional schemes imagine.

From observing the retarded relaxation of muscles in hypothyroidism, it is clear that low energy makes relaxation difficult.

Szent-Gyorgyi showed that muscle in rigor mortis softened when placed in ATP solution.

The failing heart becomes stiff.

Stretching a muscle increases its ATP.

Increasing the concentration of sodium, ATP, carbon dioxide, ... in the cell's environment increases its ATP content.

Filling the heart stretches it, increasing its ability to beat.

Understanding the silliness of the "pump" idea demystifies the membrane idea, and then a person can begin to think about how cells really work.

Stimulated, active cells expend energy. Besides doing measurable work, such as contraction, they release a measurable amount of heat, at the moment of responding to stimulation. Surprisingly, stimulated nerves have been observed to absorb heat immediately after releasing it, in a "refrigerator-like" process that coincides with their electrical repolarization. No one was able to explain this on the basis of membranes and pumps, since the pumps should be releasing their heat *after stimulation and during repolarization.*

I have thought of this in terms of Kelvin's idea of increased surface area leading to decreased temperature. What we need, in order to understand the way energy can be used in reestablishing the cell's resting condition without releasing heat, might be the idea that physical processes (the change of protein conformation and water structure) are intimately integrated with chemical equilibria.

Around 1970, a famous English researcher was in Eugene lecturing about his theory that the famous "high energy bond of ATP" (14 kcal, I think he said) could be used to explain muscle contraction. I had just read an old paper by one of my professors, Sidney Bernhard, which showed that its bond energy wasn't nearly so high. When I asked Bernhard why "everyone talks about ATP's high-energy bond," he just said "everyone doesn't."

When ATP breaks down it absorbs water, and when it is synthesized, water is released. In a water-free environment, the equilibrium favors the formation of ATP. The chemical activity of water in cells is lower than it is in ordinary water. Given the right (anhydrous) environment, ATP will form spontaneously. As the reactants form ATP and give up water, energy is (at least theoretically) absorbed by the chemical bond. In the abstract, this shows that the formation of ATP and the absorption of energy could be caused by factors that control the activity or availability of water. The protein-ATP complex is one of those water-regulating factors.

The abstract idea that ATP could be formed spontaneously by a "relaxing" cell (recovering from stimulation) goes against the idea that a "cell is a motor and ATP is the fuel." Some people have argued that the contraction occurs first, causing ATP to be split, rather than the reverse. Other examples of enzyme activation support this view, that the contraction or activation is a physical process, like releasing a spring. In the contracted

or activated state, sodium is able to enter the cell momentarily, and the presence of sodium seems to allow the ATP to be reformed. **These differences might seem subtle, but they have made an all-or-none difference in the minds of medical people deciding on therapies and diets.**

This picture of a cell as a loaded spring, or as analogous to the ion exchanger in a water-softener, is the sort of image I have in mind when I speak of "charging the system."

Several researchers have demonstrated that intravenous injections of ATP prevent death from shock, that shock depletes the ATP of the cells, and that depleted cells absorb ATP much more readily than normal cells that don't lack it. All of the biologists and biochemists (at Oregon's Institute for Molecular Biology) that I mentioned this to said it was impossible, "because ATP is highly ionized and can't cross the cell membrane."

Even when a general idea is clear and consistent with the facts, if it opposes the dominant view it needs some experiments that can hardly be understood without it.

Liver ATP is increased as a result of increasing blood sodium. An increase of only about 15% in the blood sodium, for example, caused the cells' ATP to nearly double. [R. L. Veech, et al., "Relationship of free cytoplasmic pyrophosphate to liver glucose content and total pyrophosphate to cytoplasmic phosphorylation potential," FEBS Lett. 117, K65-72, 1980.]

Sodium is an "extracellular" ion, one that binds water to itself so strongly that it is excluded from the cell under normal conditions, in which the water is dominated by the cell's structural molecules. It is only when the cell is stimulated or fatigued that it absorbs larger amounts of sodium, and the fatigued cell also absorbs an excess of water. The textbooks say "water follows sodium," but the physical reality is that sodium also follows (free) water, and that it tends to be excluded from the water of cells. **Increasing the sodium in the environment of a water-logged cell will tend to dehydrate the cell.**

This experiment, using sodium to increase ATP (especially when we remember that ATP is an effective treatment for shock) shows how hypertonic sodium might rescue a shock victim, increasing circulatory efficiency, helping to increase blood volume, restoring the cell's electrical and chemical resting state, and possibly regulating intracellular pH. [G.. B. Haycock, "The influence of sodium on growth in infancy," Pediatr. Nephrol. 7(6), 871-875, 1993.] The increasing blood volume is a "mechanical" effect that helps to make the use of hypertonic sodium culturally more acceptable, but it is really secondary to the other effects of sodium. The first water to be restored to the serum is that contained in red blood cells and the swollen endothelium. *Capillaries and small blood vessels that have been obstructed by swollen endothelial cells allow free passage of the blood, and the increased water lowers the blood's viscosity, improving its ability to deliver oxygen and glucose.* Brain swelling is reduced, and consciousness is restored. Glucose metabolism is also improved under these conditions.

Sodium causes the ATPase to produce ATP, rather than consuming it. (P.J. Garrahan and I. M. Glynn, "The incorporation of inorganic phosphate into adenosine triphosphate by reversal of the sodium pump," J. Physiol. 192, 237-256, 1967.; P. A. Dibrov, et al., "A study on Na+-coupled oxidative phosphorylation: ATP formation supported by artificially imposed delta pNa and delta pK in Vibrio alginolyticus cells," J. Bioenerg. Biomembr. 21(3), 347-357, 1989.)

The membrane-pump theory says that the cell *consumes* ATP to expel the sodium which enters, and increased external sodium increases its likelihood of entering the cell, but in reality increased external sodium causes more ATP to be produced. **The precise balance of ions seems to make the difference between consumption or production of ATP.** [L. Plesner, et al., "[32P]ATP synthesis in steady state from [32P]Pi and ADP by Na+/K+-ATPase from ox brain and pig kidney. Activation by K+," Biochim. Biophys. Acta 1040(2), 167-174, 1990.]

Remembering that the muscle protein is an ATPase, there is a situation that I think is analogous. When a muscle is stretched, it forms ATP, rather than consuming it. This could be the result of a slight change in the physical state of the water and small changes in chemical affinities produced

Sodium act anti-adrenaline ↑ glucose down cell ↑ choles

by the changes in protein conformation. Before this effect of stretch on ATP synthesis was directly observed, Starling's law of the heart recognized that the force of contraction increased with the initial length of the muscle fiber. Simply increasing blood volume increases the effectiveness of the heart contraction. Szent-Gyorgyi described a related process (the "staircase" phenomenon) as "function building structure, structure producing function."

Sodium is required for cells to absorb glucose and amino acids. I have recommended salty foods at bedtime to promote sleep, because of sodium's recognized anti-adrenalin effect. There are some complicated ways of thinking about its effect on adrenalin, as there are for explaining its thermogenic effect, but the simple fact that it is needed for absorbing glucose can explain its ability to lower adrenalin (since adrenalin rises when glucose is needed) and to increase heat production.

In the fetus and the newborn baby, sodium promotes growth. Progesterone, sodium and glucose are often limiting factors in the growth of the baby's brain; when they are deficient, cells die instead of growing.

The fact is that sodium energizes. It helps to remove calcium from the cell, to produce ATP, and to promote absorption of glucose and amino acids. The fear many physicians have of injecting hypertonic sodium chloride is odd, in the light of the knowledge that has accumulated in recent decades. Chloride isn't always the ideal anion, but more elaborate preparation is needed for providing the ideal ionic solution.

Carbon dioxide is powerfully involved in the regulation of both sodium and calcium, as well as in respiration and energy production.

It tends to relax both nerves and muscles. It is apparently one of the essential factors in preventing edema. [For example, in the cornea; M. V. Riley, et al., 1995.]

ATP and CO2 both bind to hemoglobin, regulating its affinity for oxygen. The way in which they bind to this protein indicates that they will bind to many other intracellular proteins, similarly regulating the functions of those proteins.

The elimination of water from the environment in which ATP is formed or decomposed favors its formation, and in this environment ATP doesn't contain its reputed "high energy bonds," but it still has its strong affinity for binding to proteins. Sodium binds water to itself, and it is this feature that leads to its exclusion from the normal cell. CO2, when it is in water, especially with the carbonic anhydrase enzymes, combines with water. As it is formed in the mitochondria, this means that it will carry water (as well as calcium and sodium) out into the cytoplasm, and out of the cell.

In many situations, including brain hypoxia, carbon dioxide is the decisive protective factor.

Low thyroid function involves reduced formation of carbon dioxide, and the body fluids don't retain as much sodium as in normal individuals. Both urine and sweat tend to contain abnormally high sodium concentration in hypothyroidism. Because CO2 is central to the regulation of pH, and hydrogen ion excretion (acid urine) is one mechanism involved in sodium retention, the CO2 deficiency of hypothyroidism is probably closely connected with the inability to retain adequate sodium.

The body fluids are actually hypotonic in hypothyroidism.

If hypertonic sodium energizes, then the low-sodium hypoosmotic fluids of hypothyroidism de-energize.

Low-thyroid cells are also unable to retain magnesium efficiently, and a magnesium deficiency prevents muscle relaxation, wasting energy. Adequate sodium prevents urinary magnesium loss.

Hypothyroidism tends to cause hypoglycemia, and the lack of glucose (even if it is because the glucose in the blood can't be absorbed because of insufficient sodium) causes elevation of adrenalin. Hypertonic sodium given intravenously lowers the amount of adrenalin in the blood, just as the thyroid hormone does.

Hypothyroidism also causes an imbalance between the antiestrogenic antishock hormones, progesterone and pregnenolone, and proshock estrogen.

The close integration of physical and chemical processes when those processes are near

equilibrium is the fact or the principle that is lacking in the doctrine that the cell is like a collection of motors, fueled by ATP. If you can imagine a Chevrolet that at times creates gasoline while absorbing heat, then the simile would be acceptable. The inappropriateness of the mental image of a cell with pumps and motors leads to the treatment of shock with things that produce shock, of heart failure with things that produce heart failure, and of aging with things that accelerate aging.

NOTE: *The estrogen dominance which is needed to start the reproductive cycle, with cell proliferation in the endometrium, breast, and pituitary, is not otherwise useful to the organism, and is controlled and opposed during pregnancy by a constantly rising production of progesterone. The state of estrogen dominance is essentially unstable. P. T. Ellison, emphasizing the "energy hungry brains" of primates, explains the need for the massive endometrial growth in primates, and Strassman observes that endometrial regression occurs in all mammals. These are important points. Their failure to point out that estrogen has many undesirable systemic effects very likely results from the cultural context that has been created by the estrogen-promoting pharmaceutical industry.

The group of processes that we call the immune system is so deeply integrated with everything else in the organism that to talk about "the reason for evolving it" is as misleading as to talk about "the reason" for evolving certain pigmentations–black feathers, for example, are mechanically stronger than white ones, selection of foxes for domesticability changes their fur pigmentation and their voice, selection for egg laying somehow produces suppression of feather pigmentation, etc., yet people like to talk about protective coloration, because an easy connection can be made between that and genetic selection. Being an organism is a problem whose solution may require inventive use of internal and external resources; chromosomes are internal resources, not clusters of traits.

The ideology that sees the organism as a sum of traits, each with its gene, has been a failure in providing understanding about how an organism comes to exist.

Regeneration and the Anti-adaptogens

I don't think aging is necessary, and I think I have begun to see the organism in a context that can explain the cause of aging in a relatively simple way.

In outline, this is how I see it:

1. Every cell and tissue is capable of renewal;

2. the (Hayflick) doctrine of absolutely limited cellular renewal capacity has been disproved in many ways;

3. the great variety of degenerative diseases which can be promoted by a few factors--radiation, oxygen deprivation, polyunsaturated fats, and estrogen--can serve as a guide to the nature of our basic control systems;

4. the factors which disrupt our natural regulatory systems contain clues to possible restorative methods.

Every important issue in life is an opportunity for powerful self-interest to intervene and take control. In transportation, corporations interested in selling gasoline and cars destroyed the cities' elegant systems of electric trolleys, in energy the nuclear and petroleum interests fought the development of solar and wind power, and the timber industry lobbies against innovation in house construction. The issue of aging and death is one that has been consciously dealt with throughout human existence, and it has accumulated a most complex system of mental commitments. This investment of emotion and belief affects every aspect of theory and practice in biology and medicine. We have to keep asking "is this researcher ignoring some facts that might seem to conflict with his ideology?"

Definitions:

Hayflick limit: Leonard Hayflick found that certain animal or human cells which can be grown in a dish would die out after 50 divisions, and he announced that this limited ability to divide sets the maximum limit of the lifespan. He has said that this is governed by the principle that entropy tends to increase. Another group found that the same kind of cell continued to divide nicely after 110 divisions, and didn't begin to die out until they began to use the serum from a different calf. The cells of the skin and bowel divide thousands of times in a normal lifetime, and transplanted pieces of skin or mammary gland remained healthy through the lifetimes of ten animals in series.

Telomere: A structure on the ends of chromosomes that gets shorter with each division in some cells. The enzyme telomerase reconstitutes the telomeres in "immortal cells," such as germ cells and cancer cells. In aging, most aspects of cell function are weakened, but this particular enzyme operates in a location close enough to "the genes" that some people think it is behind the "Hayflick limit." But many other repair systems also slow down with aging; nothing gives this structure special explanatory power.

Previously, I have talked about the doctrine that our cells are divided into the immortal cells of "the germ line," and the mortal "somatic" cells of all the rest of the body. This doctrine says "people

are mortal, so their cells must be intrinsically mortal, but they can have descendants ad infinitum, so their germ cells must be different from all the rest of their cells, and immortal." Alexis Carrel was famous for demonstrating that heart cells could be immortal in the right environment, but his work is now ignored or dismissed. "Only cancer cells and the germ line are immortal," the present doctrine says; ("and maybe embryonic cells"). It seems that the immortalization of our mortal somatic cells is acceptable, as long as these cells have the function of killing us.

I think some of Carrel's ideas about the nature of living organization and of aging are worth quoting. (Man the Unknown, 1935.)

"Isolated cells have the singular power of reproducing...the edifices characterizing each organ. If a few red corpuscles, impelled by gravity, flow from a drop of blood placed in liquid plasma and form a tiny stream, banks are soon built up. Then, these banks cover themselves with filaments of fibrin, and the stream becomes a pipe, through which the red cells glide just as in a blood vessel. Next, leucocytes come, adhere to the surface of the pipe, and surround it with their undulating membrane. The blood stream now assumes the appearance of a capillary vessel enveloped in a layer of contractile cells. Thus, isolated red and white corpuscles manage to construct a segment of circulatory apparatus, although there is neither heart, circulation, nor tissues to be irrigated." "The spontaneous tendency toward formation of the organs by their constitutive cells, like the social aptitude of the insects, is a primary datum of observation." (Page 107.)

"The simplest system, where the phenomenon of sensescence is observed, consists of a group of tissue cells cultivated in a small volume of nutritive medium. In such a system, the medium is progressively modified by the products of nutrition and, in its turn, modifies the cells. Then appear senescence and death. The rhythm of physiological time depends on the relations between the tissues and their medium. It varies according to the volume, the metabolic activity, the nature of the cell colony, and the quantity and the chemical composition of the fluid and gaseous media. The technique used in the preparation of a culture accounts for the rhythm of life of such culture. For example, a fragment of heart fed with a single drop of plasma in the confined atmosphere of a hollow slide, and another one immersed in a flask containing a large volume of nutritive fluids and gases, have quite different fates. The rate of accumulation of the waste products in the medium, and the nature of these products, determine the characteristics of the duration of the tissues. When the composition of the medium is maintained constant, the cell colonies remain indefinitely in the same state of activity." "If, by an appropriate technique, their volume is prevented from increasing, they never grow old. Colonies obtained from a heart fragment removed in January, 1912, from a chick embryo, are growing as actively today as twenty-three years ago. In fact, they are immortal." (Page 173.)

Heart cells are recognizable even in isolation, because they beat. It would be impossible to mistake them for another type of cell.

Years later, Hans Selye was observing the reaction to a small glass tube inserted under a rat's skin. He noticed that the tube was soon enclosed by a capsule of fibrous tissue, and that the cells gradually grew in a strand from the ends down the channel of the tube. These cells were isolated from the fluids that normally surround cells, and Selye found that after a short time they took on the appearance of cells from a very old animal, while the cells of the surrounding capsule remained normal. Selye drained the fluid at intervals, allowing it to be replaced by fresh fluid, and found that at the end of the rat's life-span, the cells of this filament showed no signs of aging.

Carrel's work with tissue-culture led him to believe that changes in the organism's fluids were a major part of the aging process. Extracts from animal embryos have been used medically for treating old people, because of their confirmed effect on cell function. "Blood plasma alone displays, throughout the entire life-time, progressive modifications characterizing the senescence of the body as a whole. We know that it contains the secretions of all tissues and organs. Plasma and tissues being a closed system, any alteration in the tissues reacts on the plasma, and vice versa. During the course of life, this system undergoes

continuous changes. Some of these changes may be detected both by chemical analysis and by physiological reactions. The plasma or the serum of an aging animal has been found to increase its restraining effect on the growth of cell colonies. The ratio of the area of a colony living in serum, to that of an identical colony living in a saline solution and acting as a control, is called the growth index. The older the animal to which the serum belongs, the smaller is this index." "During the first days of life, blood serum does not inhibit the growth of cell colonies any more than does the control solution. At this moment the value of this index approaches unity. As the animal becomes older, its serum restrains cell multiplication more effectively. And the index decreases. During the last years of life, it is generally equal to zero." {Page 168.)

In 1921, a researcher (A. J. Lotka) looking for a job at the Rockefeller Institute visited Carrel's laboratory. "I saw a young lady making chicken hash in the most heartless but thoroughly scientific manner. I saw a little piece of chicken heart foolishly throbbing after all occasion for throbs had long ceased. I saw a thirteen year old dog rejuventated by the infusion of younger blood. It was hardly converted into a giddy young thing, but they told me there was still marked improvement even after twelve months." (S. E. Kingsland, *Modeling Nature*, Univ. of Chicago Press, 1995.)

Carrel discussed Lecomte du Nouy's equations for describing the regenerative activity of the body at a given age. (A 21 year-old person heals twice as quickly as a 40 year-old person.) The rate of healing and the growth index of plasma, according to Carrel, **"...correspond to successive states in the chemical composition of the humors. The proteins of blood serum become more abundant and their characters are modified. It is chiefly the fats which give to serum the property of acting upon certain cell types and of diminishing the rapidity of their multiplication. These fats increase in quantity and change in nature during life."** (Page 174.)

Here, I want to review some of the effects of fats that I have talked about elsewhere. Polezhaev's work in regeneration has suggested that the fatty residue left from degenerating cells stimulates the formation of new cells. Linoleic acid, like phorbol esters and estrogen, activates protein kinase C, and the cell growth system.

In looking at a tissue slide that was used to diagnose "ductal carcinoma in situ," I noticed that the structures resembled cross-sections of tubercles. In the breast ducts, fatty residues from milk secretions should be able to stimulate cell division. The fats formed by the tuberculosis bacillus stimulate the cellular reaction that produces the tubercle structure. Since a tuberculous breast grossly resembles a cancerous breast, it is important that the possible structural similarity of the two diseases, under the microscope, be considered. The bacteria can disappear from the cells in a tubercle, and the "defining" presence of giant cells in the tubercular lesion isn't invariable.)

It has been suggested that the tubercle develops and persists because the body's proteolytic enzymes are inhibited by the unsaturated fats. (Even older ideas of "fatty degeneration," going back to the very beginnings of biochemistry, were based on the fact that proteins are deposited from solution at an interface, such as that formed by a drop of oil, forming a sort of proteinaceous skin around fat droplets.) Whether the process is simply the result of inactivating proteolytic enzymes, or the result of a more specific disordering of cell control systems, it is a well established experimental fact that oils stimulate a kind of fibrous tumor, called the "oil granuloma." If the oil can't be digested and removed, the body reacts by forming a growth around it. Inside the cell, unsaturated fatty acids slow many cellular processes, including respiratory energy production and protein turnover, changes which parallel the changes occurring in aging.

About 30 years ago, Leonard Hayflick found that certain animal or human cells which can be grown in a dish would die out after about 50 divisions. He also found that cells from old individuals would stop dividing sooner when grown in tissue culture. He announced that this limited ability to divide sets the maximum limit of the lifespan. He has said that this is governed by the principle that entropy tends to increase. Another group found that the same kind of cell continued to divide nicely after 110 divisions, and didn't begin to

die out until they began to use the serum from a different calf. Their result resembled Carrel's findings, in which the fluid from younger organisms supported more vigorous growth in tissue culture, and clearly casts doubt on Hayflick's principle. But even without such contradictions of Hayflick's tissue culture results, Hayflick's claims couldn't really be taken seriously as anything but a theoretical model of what is happening to cells in an aging organism, because cells that are removed from their complex environment in the organism have been deprived of a rich and communicative framework.

The cells of the skin and bowel divide thousands of times in a normal lifetime, showing that there is a kind of arrogant silliness in the claim that "human cells have a strictly limited capacity to divide." (I call this "disproof by dandruff.")

Pieces of skin or mammary gland, removed from old rats and transplanted into young rats, remained healthy through the lifetimes of ten animals in series. When young animals have been surgically attached to old animals ("parabiosis"), the pair has lived out the life-span of the younger animal, allowing the older one to reach an abnormally advanced age. In some studies, beneficial changes have been seen in the old individual, and some harmful effects appeared in the young animal. I have described these experiments previously.

Selye's experiment, besides showing the importance of fluid renewal in cell aging, also showed one of the ways in which cells respond to structure. Cells build structures, and then they respond to them. They "know" where they are in a given structure. Cells produce materials--some of them soluble, others insoluble--that produce a characteristic local environment. In plants, the cellulose scaffolding between cells, and other extracellular matrix materials, serve as part of the information that guides the functioning of cells,[1] so that removal of the cellulose allows the cell to stop a specialized function, and begin to grow and take on new functions, even in some cases producing a complete new organism. In a wound in an animal's skin, cell division is stimulated to heal the wound. I think it is the doctrine of the germ line/somatic distinction that has prevented more vigorous research in the origin of teratomas, growths of radically different tissue types (hair, teeth, bones, fingernails, mammary tissue, e.g.) in an inappropriate location--often the ovary, but sometimes in the bladder, tongue, rectum or other location. These have been explained as "embryonic rests," or undeveloped Siamese twins, as a way to avoid the idea that somatic cells have the capacity to revert to totipotency. Their occurrence is strongly reminiscent of the situation in plants, in which an injured (isolated) somatic cell becomes "totipotent," resembling a germ cell or embryonic cell.

If cells have systems that regulate their functions, and known substances distrupt those functions, the endogenous regulatory material must have some of the properties of the disruptive material. For example, digitalis and ouabain are plant steroid-derivatives that are poisonous to animal cells--especially the heart cells--by acting at a "site" which is normally regulated by substances such as DHEA and progesterone.

For plants, cholesterol is a hormone, while it is only a precursor for hormones in animals. If plants ate animals, they might eventually accumulate enough cholesterol to disrupt the processes normally regulated by their very small amounts of cholesterol.

The fact that opium from poppies, and similar substances found in other plants, have a powerful effect on animals, and can be found associated with certain sites in their cells, led to the belief that these were regulatory sites, that might normally be controlled by very small amounts of materials produced in the animals' tissues, for regulatory purposes. This led to the discovery of the endorphins, the peptide molecules that have morphine-like effects.

Valium (or the traditional valerian root extract) was found to be associated with a certain "receptor site," which is now known as the "benzodiazepine receptor." A peptide called "endozepine" is one of the natural regulators of that control system, but it is also influenced by GABA (gamma amino butyric acid), progesterone, pregnenolone, and other materials. Butyric acid itself might affect this system.

Marihuana acts on cells by acting at a site that is called the "cannabinoid receptor," because the

Recepteur Zodiazepine = valium, valerian Root, Endozepine Regulariser le syst de recepteur Zodiazepine et endiazepine est influencé par GABA, Proges

body's natural regulator acting on that site isn't yet known.

The unsaturated fatty acids, linolenic acid and linoleic acid, produced by plants, interfere with intercellular communication,[2] as well as intracellular regulatory sites. (PKC, osmotic balance[3], respiration.) The body's natural regulatory materials are probably similar in structure, but produced in controlled amounts and locations.

The Mead acids are unsaturated fatty acids produced in small quantities by the body when the diet doesn't contain an overwhelming amount of the plant-derived fatty acids. Wherever the plant fats act, we can expect to find a process that is regulated by the Mead acids, though not necessarily in the same way or with the same result. Even if the materials had the same effect on the control system, the increasing accumulation of an active material will tend to make control impossible, acting as a constant signal to activate the system. (Therefore, even an exaggerated accumulation of the natural transmitter substance would be disruptive if it were released in an uncontrolled way. The regulatory substance ideally would not be stored in excess, or it would be released in a controlled way. The Mead acids seem to meet these criteria.) [The position of the certain type of fatty acid on glycerol, for example, is regulated by specific enzymes.]

A naturally occurring combination of a fatty acid with ethanolamine, called anandamide, activates the "marihuana receptor" of cells. It prevents some types of cell activation. The Mead acid ethanolamide, like the arachidonic acid form, can be enzymatically formed in various human tissues, such as the hippocampus, but the two substances have slightly different effects. Marihuana's anticonvulsant properties might be more effectively represented by the Mead acid derivative. The anti-excitatory effect might also be effective in preventing the loss of cells in the hippocampus, hypothalamus, and other brain regions, which (building on Olney's work 25 years ago) is increasingly understood to result from excitotoxicity.

The architecture of tissues interacts with the cytoskeleton and the nuclear scaffolding to define the possibilities and opportunities that are available to the cell and to the organism.

The organization of life is maintained by the energy it uses, and the use of energy requires a specific organization. There are processes in cells that regulate the interactions of growth, division and other functions, but these processes are responsive to the cells' environment--they aren't just "emitted by" or "unrolled from" the cells' repertoire of abilities.

The cell's structure has sensitive "leverage" points that serve for purposes of "perception" or "signalling." When organization fails, it is just reasonable to consider whether extraneous conditions or "signals" have intervened. If it were in life's nature to become disorganized, it is hard to imagine that it would persist and thrive.

Optimizing respiration

In a given situation, people who eat more are healthier and live longer than those who eat less--their bodies burn calories vigorously. In one study, fat people were found to be able to maintain their weight on only 700 calories per day, about a third of a normal calorie intake. In animal studies, too, the fast-metabolizers live longer than the animals that don't burn calories so fast. When animals are fed a calorie-restricted diet, and live longer than their *ad lib* fed relatives, people like to say that their "metabolic rate is depressed," but that isn't true: the under-fed animals are *smaller* than the *ad lib* eaters, but **each gram of their tissue burns energy at a higher rate.**

The biological value of the antioxidants is that they allow oxygen to be used productively, rather than destructively. When something interferes with the normal, productive use of oxygen, there is a great increase in the destructive forms of oxidation, such as lipid peroxidation, and the antioxidative reserves become crucial. That is, decreased respiration of the productive sort tends to increase the destructive use of oxygen.

Respiration in the ordinary sense is breathing, the exchange of gases between the animal and its environment.

Tissue respiration refers to the absorption of oxygen from the blood by cells, or, more exactly, to the exchange of gases between cells and their environment. Plants and other organisms respire in ways that are biochemically very similar to our tissue respiration.

Not all the oxygen we consume is put to good use, and we sometimes produce exhalations of gases other than carbon dioxide and water vapor.

Optimizing respiration means increasing the uses of oxygen that provide energy and increase functional capacity, while decreasing the forms of oxidation that impair functioning and decrease the production of useful energy.

In general, things which are associated with energy-producing respiration (such as thyroid hormone, carbon dioxide, coconut oil) also have roles as "antioxidants."

In 1895 Magnus-Levy demonstrated that hypothyroid people have abnormally low heat production, and that their heat production could be brought up to normal by giving them thyroid substance. In 1926, Otto Warburg showed that the respiratory enzyme, containing the heme group, is inhibited by carbon monoxide, which binds to that enzyme, as it does to hemoglobin. Warburg also showed that visible light restores the activity of the respiratory enzyme by dissociating it from the carbon monoxide. Beginning in the 1930s, many substances were found that blocked respiration and

Under stressful conditions, people may exhale measurable amounts of pentane, ethane, isoprene, carbon monoxide, and other substances with potential toxicity.

In hyperventilation, so much carbon dioxide is lost in the breath that our tissue respiration is impaired, creating a partial "tissue suffocation."

If cells consume oxygen without producing carbon dioxide generously, a situation analogous to hyperventilation/tissue suffocation exists.

Oxygen deprivation is one of the signals that stimulates the production of new red blood cells, and this involves the production of porphyrin, heme, and hemoglobin.

The elimination of heme by oxidation produces carbon monoxide, which can block the respiratory production of energy.

The heme group (of hemoglobin and the respiratory enzymes, for example) is the iron-binding oily molecule that interacts with oxygen, and it is called a porphyrin. There is a long history of investigating the interactions of porphyrin metabolism with estrogen (L. C. Strong, "Sex differences in pigment content of Harderian glands of mice," *Proc. Soc. Exp. Biol. Med. 50,* 123-125, 1942), with cancer (e.g., F. H. J. Figge, *et al., Cancer Res. 2,* 335-342, 1942), with diet, and with excess iron. Estrogens are known to cause porphyria (R. D. Levere, *Blood 28,* 569-572, 1966), and to exacerbate the symptoms and biochemical disturbances in people with subclinical porphyria. Sometimes symptoms occur premenstrually, during the time of increased estrogen production--the term "ovulocyclic porphyria" has been in use for a long time. Puberty therefore increases the susceptibility to symptomatic episodes. Jaundice in pregnancy and in oral contraceptive users is probably a closely related phenomenon. (H. F. von Oldershausen, *Deutsch. Med.J. 19,* 394-403, May 15, 1968.)

Porphyrin synthesis begins at an important cross-over point of protein and carbohydrate metabolism. Succinyl CoA and amino levulinic acid can enter the Krebs cycle or the porphyrin pathway. Protein catabolism feeds into these pathways. Increased protein catabolism or blockage of oxidative consumption of Krebs cycle fuel--for example by poisoning--makes these precursors available to enter the porphyrin pathway. Stress-induced oxidation of heme can eliminate feedback control, but the *specific* outcome can be modified in many ways.

Low blood sugar, most often caused by hypothyroidism, and diabetes--which involves poor absorption of sugar by cells--both tend to lower the respiratory quotient, the amount of carbon dioxide produced in relation to the amount of oxygen used. High carbohydrate diets, sometimes with insulin, have been used to treat porphyria (Perlroth, et al., Waxman, et al.). The use of carbon dioxide inhalation in psychiatry has many metabolic justifications, one of which might be the importance of carbon dioxide in glucose regeneration. It is also essential for detoxifying ammonia. Whenever a symptom is relieved by glucose, I think we should suspect that thyroid and carbon dioxide might be deficient.

Many serious long-range consequences of excess heme/porphyrin production and metabolism are currently being investigated, suggesting that the criterion of "twice the upper limit of normal" excretion that was recently proposed by a government agency, for recognizing that a problem exists, could allow far more serious problems to develop over time, that on the surface might seem unrelated to porphyria. I consider any porphyrin excess to be a serious indicator of physiological stress. **The ramifications of disturbed heme metabolism, resulting from exogenous factors, are far-reaching. For example, G. Y. Kennedy, at the Cancer Research Laboratory, University of Sheffield, observed that a porphyrin shortened the time required to induce tumors, and porphyrin derivatives have been proposed to be "cancer hormones."** The carbon monoxide produced in the breakdown of heme inhibits many enzymes. The consequences of slight excesses in porphyrin metabolism just haven't been investigated, because of the genetic dogmatism that denies that the person's environment could be at fault.

The synthesis of heme/porphyrin, and the production of red blood cells, are stimulated by a lack of oxygen, or by toxins such as arsenic and iron, which cause oxidative stress. Emphysema, high elevation, sluggish circulation, and nocturnal breathing problems can cause enough oxygen deficiency to stimulate the formation of new red blood cells. Newborn babies often have polycythemia, as a result of limited prenatal oxygen supply. At a certain point, the continued production of red blood cells can make the blood so viscous that this viscosity impairs circulation through capillaries, and creates a vicious circle, stimulating the formation of more red blood cells. Men are more likely than women to have polycythemia rubra vera, possibly because testosterone is anabolic to the bone marrow, and estrogen tends to slow blood cell formation (females of all species are relatively "anemic," compared to males, partly because their blood is more dilute), but I think the greater ability of men's marrow to respond proliferatively to hypoxia is influenced by many factors, including

11-9-98 ☆ Bilirubin v respiration cellular

increased mucopolysaccharides in the skin (O. Braun-Falco, *Derm. Wschr. 136,* 1085, 1957). This is reminiscent of hypothyroid myxedema; it has been suggested that mucopolysaccharides can act as a matrix for calcification (W, C. Johnson, et al., *J. Invest.Derm. 43,* 453, 1964). Estrogen stimulates the formation of collagen (Loeb, et al.), and increases its age-like properties, and progesterone opposes some of these pro-aging effects on connective tissues. Mere lack of oxygen stimulates collagen formation (Chvapil, et al.), and the opposing effects of estrogen and progesterone on tissue oxygenation can account for many of the tissue changes they produce.

Oxygen deprivation causes tissues to retain calcium (and iron), as does estrogen in many cases, being similar to aging in promoting cellular uptake of calcium. Since the porphyrins strongly bind metals, it has been suggested that they may have a role in mediating the deposition of metals in stressed tissues. Paroxysmal vasospasm occurs in about 90% of scleroderma patients, and estrogen and adrenalin are known to synergize in producing vascular spasm; **hypothyroidism normally involves elevations of both estrogen and adrenalin.**

The porphyrins break down into bilirubin, which also poisons mitochondrial respiration (Zetterstrom and Ernster).

I have known women who developed scleroderma after beginning the use of estrogen, and who were reluctant to stop, because they had been told that estrogen would protect them from osteoporosis and heart disease. Men who have had a diagnosis of scleroderma have told me that with the use of thyroid and magnesium supplements, epsom salts baths, and topical progesterone and vitamin E, their symptoms regressed. I suspect that carbon dioxide produced in mitochondria is the main factor in removing calcium from them.

Polymyositis sometimes leads to calcification, and **this would be expected if the problem is related to mitochondrial respiration, as is now generally thought to be the case;** thyroid and magnesium are often the factors needed to normalize mitochondria and prevent calcification. In general, fatigued cells take up calcium and lose magnesium.

Many people get minor bony excrescences (bone spurs, osteophytes, exostoses, hyperostoses) during puberty or menopause, or at other times of hormone imbalance, which often disappear spontaneously. This would have very little to do with the severe oxygen deficiency states in which collagen synthesis is overstimulated and general calcification occurs. Growth hormone and prolactin imbalances have been suspected to have a role in some of these growths, and cortisol--which is is active in several aspects of bone metabolism--is probably involved (all of these hormones are elevated by estrogen, and hypothyroidism is often responsible.) Progesterone, thyroid, bromocriptine, and other things are available to normalize the pituitary, when that is malfunctioning. The bone spurs that develop during times of fluctuating thyroid function, might also be promoted by rapid changes in calcium and carbon dioxide levels. (The description of bone mineral as "apatite" leads many people to forget its carbonate content.)

In general, lactic acid in the blood can be taken as a sign of defective respiration, since the breakdown of glucose to lactic acid increases to make up for deficient oxidative energy production. Normal aging seems to involve a tendency toward excess lactic acid production, and age-pigment is known to activate the process. Eliminating respiratory toxins (such as unsaturated oils, estrogenic and antithyroid substances, lead, and excess iron) is the most obvious first step to take when there is excess lactic acid formation. Carbon dioxide supplements have been shown experimentally to reduce residual lactate production. Many people experience exhilaration when they go to very high altitudes, and it is known that people generally burn calories faster at high altitude. **It has been found that, during intense exercise (which always produces a lactic acid accumulation in the blood), a lower peak accumulation of lactate occurs at high altitude, and this seems to be caused by a reduction in the rate of glycolysis, or glucose consumption.** (B.Grassi, et al.) Since there is less oxygen at high elevation, and since oxygen is used to consume lactic acid, this effect is the opposite of what many people expected. In some sense, respiration becomes more efficient at high altitude. Youth and increased

times supported the process by helping to stabilize the high energy metabolism of the brain, and even by stabilizing the "energized" state of water that supports brain efficiency. Roman Schmitt has proposed that, 66 million years ago when dinosaurs became extinct and mammals began their rapid evolution, "at that time hydrothermal venting went wild," releasing huge volumes of carbon dioxide and other substances into the atmosphere.

Antarctic ice cores show there were large increases in atmospheric carbon dioxide in relatively recent times: 10,200, 11,600, and 12,900 years ago, and two broad peaks in carbon dioxide release occurred just 4,200 and 7,700 years ago. (Figge and White.) Local or regional increases in carbon dioxide from volcanism could have more continuous effects on brain development.

In times of lower atmospheric carbon dioxide, our Krebs cycle still produces it internally, and the rapid development of the brain during gestation takes advantage of the high concentration of carbon dioxide in the uterus. (These ideas make me doubt the safety of the rapid breathing encouraged by some obstetricians.)

A weakened ability to oxidatively produce energy can lead to the maladaptive over-production of collagen, porphyrins, red blood cells, and other tissues and substances, which in turn can lead to many adaptive and maladaptive changes. I think skin and mucous membranes provide a good illustration of the way respiratory potential influences structure: Estrogen-increased keratinization is opposed by vitamin A, which increases the proportion of active, differentiated cells.

Changes that begin as functional adaptive processes can lead to structural and anatomical changes that contribute to functional derangements. *If we look at small anatomical structures such as capillaries, we can see that our anatomy is in flux, adjusting structures to meet changing needs.* After every experience of stress or trauma, we have to reconstitute ourselves. When this rebuilding lags, defects accumulate. Rosacea, diabetes, and systemic lupus erythematosa are examples of conditions that progress from functional to anatomical abnormalities.

Our organization is built on the basis of interacting structures and functions. Adequate respiration depends on adequate structures, and adequate structures require adequate respiration.

Anatomical structures, tubes, spheres, and sheets of cells, create gradients and fields as materials move through them, in relation to which cells organize themselves. Changes in simple electrical fields can cause radical changes in the behavior of cells. Changes in respiration cause many changes in chemical and electrical gradients, and the intensity of respiration is known to be a central factor in the development and preservation of biological form. Child's work on the developmental importance of metabolic gradients (summed up in *Patterns and Problems of Development,* 1941) has been confirmed and refined, despite the immense effort that has been spent on genetic mystification of the processes that create and maintain form.

The quality of the developing brain of the fetus, the deterioration of the aging immune system, and hundreds of other processes are governed by the quality of respiration.

D-galactosamine-induced sensitivity to low-dose endotoxin. Kujawa KI, Berning A, Odeyale C, Yaffe LJ.

J Surg Res 1984 Jul;37(1):63-68 Evidence for aerobic glycolysis in lambda-carrageenan-wounded skeletal muscle. Caldwell MD, Shearer J, Morris A, Mastrofrancesco B, Henry W, Albina JE "Classically, increased lactate production in wounded tissue is ascribed to anaerobic glycolysis although its oxygen consumption has been found to be similar to normal tissue. This apparent inconsistency was studied in a standardized isolated perfused wound model. Male Sprague-Dawley rats were wounded (group W) with intramuscular injections of lambda-carrageenan and fed ad lib.; not wounded and pair fed to the decreased food intake of the wounded animals (group PFC); or not wounded and fed ad lib. (group ALC). After 5 days, the hindlimbs of animals from each group were either perfused using a standard perfusate with added [U-14C]glucose or [1-14C]pyruvate or assayed for the tissue content of lactate and pyruvate. In addition, the effect of a 30% hemorrhage on the tissue lactate and pyruvate concentration was examined. **Wounding increased glucose uptake and lactate production by 100 and 96%, respectively, above that seen in ALC animals.** Oxygen consumption was unchanged by wounding (5.74, 5.14, and 5.83 mumole/min/100 g in W, PFC, and ALC, respectively). Glucose and pyruvate oxidation were also unaltered among the groups. Hemorrhage resulted in a comparable increase in lactate and pyruvate in tissue from wounded and pair-fed control animals (above those concentrations found in tissue harvested without preexisting hemorrhage). As a consequence, the same relationship in L/P ratio was maintained after hemorrhage. Taken together, these results confirm the **presence of aerobic glycolysis in wounded tissue** (unchanged oxygen consumption, glucose, and pyruvate oxidation). In addition, pyruvate dehydrogenase activity in the wound was apparently the same as that found in muscle from pair-fed control animals."

Food Chem Toxicol 1984 Aug;22(8):615-621 Effect of orally administered food-grade carrageenans on antibody-mediated and cell-mediated immunity in the inbred rat. Nicklin S, Miller K "Experiments were performed to investigate the immunological consequences associated with the persorption of poorly degradable carregeenans from the diet. Using an inbred strain of rat it was demonstrated histochemically, by the carrageenan-specific Alcian blue staining technique, that **small quantities of food-grade carrageenans given at 0.5% in drinking-water for 90 days could penetrate the intestinal barrier of adult animals. This apparently occurred via an intact mucosa in the absence of inflammatory or pathological lesions. The carrageenan was demonstrated in macrophage-like cells present within the villi and lamina propria of the small intestine.** The oral administration of kappa, lambda or food-grade carrageenans did not affect local (biliary) or antibody responses to gut commensal microorganisms, or to orally-administered sheep erythrocytes. However, when sheep red blood cells were administered parenterally the ensuing anti-sheep red blood cell haemagglutinating antibody response was temporarily suppressed in carrageenan-fed rats. lambda-Carrageenan and iota-carrageenan both significantly (P less than or equal to 0.01 and P less than or equal to 0.05, respectively) reduced the mid-phase (14-28 days) haemagglutinin response; kappa-carrageenan (L100) was less effective but caused significant depression at day 21 (P less than or equal to 0.01). Individual responses were, however, within the control range 35 days after sheep erythrocyte administration, thus indicating the temporary nature of this effect. Although carrageenan administration depressed the anti-sheep erythrocyte antibody response, it did not affect T-cell immune competence as measured by the popliteal lymph node assay for graft-versus-host reactivity."

J Nutr 1986 Feb;116(2):223-232 Effects of certain dietary fibers on apparent permeability of the rat intestine. Shiau SY, Chang GW "Apparent intestinal permeability was determined indirectly by orally administering a poorly absorbed dye, phenol red, to rats and measuring its recovery in feces and in urine. Increased apparent permeability was recognized by increased dye recovery in urine and by an increased ratio of urinary to fecal dye recovery. Guar gum, pectin, carrageenan type I (80% kappa, 20% lambda), carrageenan type II (iota) and cellulose were each fed at levels of 5 and 15% (wt/wt) of the diet for 31 d to male Fischer 344 rats. The average initial weight of rats was 230 g. Rats fed 15% guar gum gained significantly less weight than most of the other rats (P less than 0.05). Phenol red recovery was measured at 2 and 4 wk after the beginning of the experiment. **At 2 wk urinary recoveries of phenol red were high in rats fed fiber-free and carrageenan type II diets, indicating increased apparent permeability.** By 4 wk, adaptation had apparently taken place." "These data are consistent with the hypothesis that intestinal permeability to foreign substances may be altered considerably by diet."

Pathologe 1993 Sep;14(5):247-252 [Persorption of microparticles].[Article in German] Volkheimer G "Solid, hard microparticles, such as starch granules, pollen, cellulose particles, fibres and crystals, whose diameters are well into the micrometre range, are incorporated regularly and in considerable numbers from the digestive tract. Motor factors play an important part in the paracellular penetration of the epithelial cell layer. From the subepithelial region the microparticles are transported away via lymph and blood vessels. They can be detected in body fluids using simple methods: only a few minutes after oral administration they can be found in the peripheral blood-stream. **We observed their passage into urine, bile, cerebrospinal fluid, the alveolar lumen, the peritoneal cavity, breast milk, and transplacentally into the fetal blood-stream. Since persorbed microparticles can embolise small vessels, this touches on microangiological problems, especially in the region of the CNS.** The long-term deposit of embolising

Progesterone, thyroid, cancer

In the first half of the twentieth century, Otto Warburg and Albert Szent-Gyorgyi proposed that proliferation is the natural "primordial" tendency of all cells, including those in complex multicellular organisms, in which many cells remain in a quiescent, non-proliferating state for years. Their orientation was similar to that of Johanes Muller, who in 1840 argued that cancer might originate at the level of tissues, rather than in the nature of the individual cells making up the tissue.

Both Warburg and Szent-Gyorgyi showed that oxidative metabolism is crucial in maintaining the relative quiescence that makes it possible for multicellular organisms to exist and to preserve their organization. In these organisms, the individual cells are embedded in a glue-like matrix, in the case of animals, or in a woody scaffolding, in the case of plants; the oxygen and nutrients needed by the cells diffuse through the matrix, so its condition is crucial for the cells' functions. The extracellular matrix, and the materials that pass through it, constitute the "field" within which cells develop and function.

Early researchers understood that the connective tissue matrix changes progressively in aging, which is evident in the fact that the meat of old animals is tougher than that of young animals. Leo Loeb, studying the effects of estrogen on the uterus, showed that it increased the formation of collagen, causing cells to be separated from their blood supply by a thickened barrier of water and collagen.

Estrogen, by altering the cell matrix, alters the developmental field itself. Simply by creating a thickened barrier, it makes it difficult for cells to maintain their proper place in the organism, and some of them, in the energy-deprived state, revert to the primordial proliferative state.

Thyroid hormone, the regulator of oxidative metabolism, is the basic hormone making possible the respiration which generates and sustains the multicellular state.

The simple idea of antagonism between hormones, for example between catabolic and anabolic steroids, or between progesterone and estrogen, is firmly based on experiments, but there is an attitude in medical endocrinology, based on the names of the substances, that insists on a "synergy" between estrogen ("the hormone of estrus, creating a readiness to copulate") and progesterone ("the hormone of pregnancy"). Sequential, coordinated action isn't the same as synergy. Hunger can lead to satiety, but no one denies that these are contrasting conditions. Hundreds of biological actions created by estrogen are reversed by progesterone, and vice versa.

Shock, capillary leakage, excessive clotting of the blood, epilepsy, goiter, hyperactivity, and countless other biological problems are created by an excess of estrogen, and normalized by progesterone. The problem of cancerization by estrogen, and its opposition by progesterone, was clearly defined by Alejandro Lipschutz more than fifty years ago, but a series of deliberate actions by the drug industry, and its "regulatory agencies," has prevented a rational and coherent approach to the use of hormones in preventing and curing cancer.

For over fifty years, estrogen has been widely promoted for the prevention and treatment of various cancers, and throughout the 20th century agents of the drug industry claimed that it was not carcinogenic, and prevented the US government from classifying it as such. During the same period, and for many of the same commercial reasons, natural progesterone has occasionally been claimed either to cause cancer, or to be ineffective in its treatment. While billions of dollars were spent in "cancer research," the useful basic knowledge about the prevention and cure of cancer was ignored. Not just ignored, but suppressed: Medical journals of all sorts have simply declined to publish favorable research on

progesterone, and medical conferences on female endocrinology that claim to be open to all views are not open to favorable reports on progesterone.

Some researchers have observed that only about one percent of medical research is scientifically sound, but that view ignores the fact that the "valid one percent" is certainly going to be misinterpreted, unless the reader understands that the medical journals are intensely subjective and biased in what they choose to publish, and that they exclude the research that would provide the essential contexts for evaluating the things that ***are*** published. To find an adequate context in which to interpret current research, we have to go back at least fifty years, to a time when the science journals were relatively independent.

The idea of "genetic determination," which I have written about many times, has been useful to the drug industry. If moderate amounts of estrogen didn't cause mutations of certain genes that were thought to distinguish normal cells from cancer cells, then how could it be carcinogenic? And if cancer cells are "genetically committed," then only lethal cytotoxic methods could be considered as therapies.

The history of estrogen and progesterone research offers an alternative view of cancer, and of physiology itself. In the 1940s, Hans Selye demonstrated that progesterone produced very deep anesthesia, and that its actions were essentially instanteous. Estrogen's characteristic actions, too (such as the uptake of water by tissues, and nervous excitation) were so rapid that it was clear that the effects were produced without the activation of special "genes." But these quick actions were generally ignored, because their existence wasn't compatible with the doctrine of genetic determination.

Estrogen acts at many different levels, modifying the state of water, of proteins and fats, of the immune, circulatory, and nervous systems. It isn't just a "carcinogen," or just a "female hormone." Many substances, processes, or conditions (cholera toxin, x-rays, oxygen deprivation) imitate many of estrogen's effects.

Energy generates order, and maintains it. Destruction of order degrades the ability of cells to produce energy.

Progesterone (and related substances), too, act on many levels of organization at the same time. The interactions of proteins and water are changed immediately, with circulatory and nervous and bioelectrical responses coinciding with changes of cells' functions, including changes in the proteins of the "receptor systems." The functional changes that can be seen in the first minutes of progesterone's actions lead to metabolic changes and then to more basic structural changes.

Stabilization and activation of mitochondria by progesterone, and a shift away from glycolysis (Joe and Ramirez, 2001: GAPDH inhibition), are exactly the opposite of estrogen's toxic effects on the mitochondria (by increasing NO, for example), and activation of glycolysis.

On the molecular level, progesterone and estrogen have different structural effects, that account for their globally opposite regulatory effects. Their systematically different effects on energy production lead to global differences in the regulation of cytokines, neurotransmitters, hormones, and cellular organelles, which contribute to macroscopic shifts in the distribution of substances throughout the organism, including water, fats, and the materials such as collagen and glycoproteins that make up the extracellular matrix.

If progesterone is to be named "the hormone of gestation," then estrogen might be called "the hormone of miscarriage."

The characteristic metabolic end-product of progesterone-dominated metabolism is carbon dioxide. During gestation, the fetus is exposed to large amounts of progesterone and carbon dioxide. The very high concentration of progesterone during gestation keeps tissues from retaining excess estrogen, even when estrogen is present in the blood stream. The very high concentration of carbon dioxide has many protective effects,

Every tumor is a biologically unique substance, but it is biologically compatible with its host. This is analogous to the tissue compatibility of twins which share a single placenta, even though they may be genetically different fraternal twins.

including protection against the formation of lactic acid.

The characteristic metabolic end-product of estrogen-dominated metabolism is lactic acid. Increasing lactic acid displaces carbon dioxide.

Carbon dioxide combines spontaneously with amine groups, as in the lysine residues of proteins, and this influences the interactions of the proteins with other substances, for example, inhibiting glycation of proteins; protein glycation occurs during stress and aging, and degrades the functions of proteins and cells and systems. These changes are believed to contribute to the hardening of connective tissues with aging.

The fibrosis of aging is associated with a generalized state of inflammation, producing catabolism and atrophy of most systems, with isolated regions escaping the general cachexia, and regenerating their cells and tissues in disorganized ways, producing many abnormalities that could be diagnosed as "precancerous," a few of which develop into tumors.

A.V. Everitt's book on the pituitary and aging mentions some studies that relate to progesterone and aging. Uterine collagen aging, which increases under the influence of estrogen, is lowest in the old rodents that have been bred the most often, and this is probably partly the result of progesterone's action on collagenase and fibroblasts, as well as its ability to displace estrogen from the tissues. Leo Loeb showed that excess estrogen and aging both produced similar increases in collagen. Alejandro Lipschutz found that chronic estrogen treatment produced fibrosis of practically all tissues, and that cancer later developed in those fibrotic tissues. Then he tested various steroids, and found that progesterone had the strongest antifibromatogenic action, and that pregnenolone was next in effectiveness. (Brief intermittent exposures to estrogen didn't produce the harmful effects, and now it's known that progesterone decreases the tissues' retention of estrogen.) Lipschutz' 1950 book on steroid hormones and tumors summarizes his work.

Contemporaries of Loeb and Lipschutz, Joseph Needham, C.H. Waddington and J.W. Orr, argued that cancer evolves through a series of developments in the tissues, rather than in single cells.

A few years later, Hans Selye showed that the partial isolation of tissue itself (for example, growing inside a small glass tube implanted in a rat) caused a tremendous acceleration of the aging process in the isolated cells and matrix. An impermeable sheet of plastic implanted in an animal tends to cause a cancer to develop, if it is folded to form a concavity. The thickened connective tissue matrix that develops with aging, irritation, and stress creates innumerable areas in which cells are similarly cut off from full contact with their normal environment.

Estrogen treatment at menopause produces alkalosis and hyperventilation. Alkalosis stimulates peroxidation and various other harmful stress-products. Prenatally, if estrogen excess doesn't kill the fetus, it retards its brain growth, because many of its metabolic actions are powerfully antigestational--actions that are used medically in the contraceptive pills and abortion pills.

All cancer cells produce lactate even in the presence of oxygen, and this increases their intracellular alkalinity, promoting swelling, calcium uptake, and proliferation. Continued exposure to lactic acid increases collagen formation and fibrosis.

I think of high altitude as analogous to the protected gestational state. (Both progesterone and carbon dioxide are increased in people adapted to high altitude.) Respiratory acidosis, meaning the retention of carbon dioxide, is very protective, and is an outstanding feature of life in the uterus. Even at the time that an embryo is implanting in the uterus, adequate carbon dioxide is crucial. Many of the mysteries of embryology and developmental biology have been explained by the presence of a high level of carbon dioxide during gestation. For example, an injury to the fetus heals without scarring, that is, with complete regeneration instead of the formation of a sort of collagenous plug. Over the last fifty years, several people have discovered that simply enclosing a wound (for example an amputated finger tip) in an air-tight compartment allows remarkably complete regeneration, even in adults, who

supposedly have lost the power of regeneration. (Exposure of tissues to air causes them to lose carbon dioxide.)

High altitude sickness is now treated with acetazolamide (which causes carbon dioxide retention, and respiratory acidosis), or with direct inhalation of carbon dioxide. Sleep apnea, which has been treated for many years with progesterone, is now being treated with acetazolamide, in recognition that it is caused by alkalosis. Both progesterone and acetazolamide increase the carbon dioxide content of the tissues, by decreasing sensitivity to carbon dioxide, yet they both stimulate respiration by increasing sensitivity to oxygen deprivation. (Wagenaar, et al., 2000.) Drugs similar to acetazolamide, sulfonamides that inhibit carbonic anhydrase, have recently been discovered to stop the growth of a wide variety of tumors.

Carbon dioxide, progesterone, and the carbonic anhydrase inhibitors stabilize and protect cells in very general ways. For example, they all inhibit epileptic seizures. All of them are involved in regulating calcium, preventing bone loss and hypercalcemia. In cancer, hypercalcemia is very common, and it is important to be able to correct it, because uncontrolled calcium is profoundly dangerous. (In "Homeostasis" and other newsletters I have written about the regulation of calcium.)

Increased intracellular calcium is excitatory, and interferes with mitochondrial energy production. Prolonged oxygen deprivation increases intracellular calcium (Smith, et al., 2001). When a cancer cell interacts with other cells, it can disturb their calcium regulation, and this can cause the cell to break its contacts with other cells (Tsuji, et al., 2002), and increased intracellular calcium can cause a cell to reorganize its intracellular structure, and to be transformed into spontaneously proliferating cells (Furst, et al., 2002). The intracellular architecture which is depolymerized by calcium excitation forms a link between the extracellular matrix and the regulation of genes in the nucleus. Generally, things (estrogen, prolactin, alkalinity, swelling, cadmium, iron) that increase intracellular calcium increase cellular proliferation. Drugs that decrease intracellular calcium are increasingly being seen to stop the proliferation of cancer cells.

Increased intracellular calcium also increases the formation of collagen, and drugs that decrease intracellular calcium decrease collagen secretion.

If cancer consists of a spontaneous process of healing and regeneration that goes wrong because of changes in its environment, because it has lost contact with its "formative field," then the only reasonable approach to the prevention and treatment of cancer is to restore that formative field. The conditions of gestation, for mammals, constitute a formative field in the highest degree that we know.

During gestation, after organs have differentiated, nerve cells extend their fibers from the brain to innervate muscles and other tissues. The special conditions of life in the uterus support this process, but something similar can happen during adult life, when damaged nerves regenerate. A major difference between injury to the fetus, and injury to an adult, is that the wound regenerates perfectly without a scar in the fetus, but in the adult, regeneration is often impaired, and a connective tissue scar replaces normally functioning tissue.

The intestinal nerves of stressed animals have been found to fragment; before the axons actually break, they form beads. (Beaded nerves are often seen in fresh tissue specimens that aren't treated by dehydration and embedding.) The surface tension of an axon has to be very low, for it to remain stable with such an extreme ratio of surface to volume: the diameter of an axon is similar to that of a bacterium. Ordinary water, with its high surface tension, breaks up into drops rather than forming a filament. If something increases the surface tension of a nerve, it tends to round up; the glial cells and Schwann cells that surround the axons of fast-acting nerves provide pregnenolone and progesterone to the axon, and the extreme lipophilicity of progesterone lowers the surface tension of cytoplasm. Progesterone powerfully improves nerve cell regeneration. During stress, cells run out of oxygen and produce lactic acid instead of carbon dioxide, and the lipophilic and acidic gas is replaced by the hydrophilic lactate.

Carbon dioxide protects nerves and muscles against excessive excitation. It inhibits lactic acid formation, and lipid peroxidation (measured in the blood) can be completely suppressed by a pCO2 of about 90 mm, which isn't high enough to produce acidosis.

Hospital respirators are normally set to hyperventilate patients, and the use of supplemental oxygen tends to make hyperventilation worse, making breathing and circulation more difficult. Carbogen, 95% oxygen with 5% carbon dioxide, is available, but is seldom used. Hyperbaric oxygen is both safer and more effective when carbon dioxide is added, but the amount of carbon dioxide needed varies with the pressure. More people would recover from brain and spinal cord injuries if physicians understood nerve and respiratory physiology.

One of the most commonly recognized features of estrogen excess is leakiness of the capillaries. Simple hyperventilation is enough to cause capillaries to leak, and this involves many related events, including decreased carbon dioxide, and increased release of serotonin. Edema, fibrosis, and inflammation (resulting from capillary leakage) contribute to a change in cellular energy production, and along with the actions of serotonin and other regulatory substances released during the alkalosis of stress, cells are stimulated to multiply.

The excitation of cells produced by a deficiency of carbon dioxide increases their need for energy. If their energy production is suppressed (as by estrogen, serotonin, and edema), they will either adapt or die.

In the isolation of a degenerating extracellular matrix, with a defective energy supply, some cells will react as though they are going to repair a wound or regenerate tissue, proliferating and degrading the damaged matrix, but instead of encountering healthy tissue, they sometimes encounter only more damaged tissue, and other cells in the simplified, proliferating state. Without finding the stable field of a healthy organism, they will continue to adapt and develop, but with reference to a field that has no function. Eventually, that kind of disoriented adaptation can produce a malignant tumor.

A 1951 Symposium on Steroids in Experimental and Clinical Practice (held in Cuernavaca), edited by Abraham White, has a chapter by Roy Hertz, et al, "Observations on the effect of progesterone on carcinoma of the cervix," that follows up on the antitumorigenic effects of progesterone discovered by Lipschutz, and the chapter includes some very interesting photographs of cervical tumors before and after treatment, and they reported that "In eleven of the 17 treated patients visible and palpable evidence of regressive alteration of the tumor mass could be demonstrated. This consisted of (a) distinct reduction in size of the visible portion of the cancer as well as reduction of the palpable extent of the mass, (b) reduction in vascularity and friability of the visible lesion with a clearly demonstrable epithelization of previously raw surfaces and (c) markedly increased pliability of the previously rigid and infiltrated parametria." *[That is, the bloody messes started healing, and the woody lumps began to feel like normal tissue.]* Despite the amazingly favorable results, they conclude "We do not consider the regressive changes observed to be sufficient to indicate the use of progesteone as a therapeutic agent in carcinoma of the cervix." This conclusion is especially interesting, considering that two pages later, Escher, et al., say that the highly ambiguous effects of estrogens on breast cancer "are of value to advanced-cancer groups." I think it's likely that the institutional sponsorship of the symposium influenced those conclusions.

Hertz, et al., gave the women 250 mg of progesterone in 5 ml of vegetable oil i.m., usually daily, for ten to 170 days. They didn't mention any side effects of sedation or anesthesia. Hans Selye found that large doses of progesterone caused profound anesthesia in rats, ***but this effect has never been reported in humans, because the pharmaceutical forms of progesterone don't permit adequate doses.*** Using progesterone dissolved in tocopherol (at 10% or 20% concentration), it takes only 100 mg to semi-anesthetize some people, and very profound anesthesia can be produced by larger doses. (In this form, a very large dose can kill a rat, though it stimulates the respiratory center at lower anesthetic doses.)

Progesterone is barely soluble in ordinary vegetable oils, and publications rarely mention that the formulations which contain 250 mg/ml also contain the "bacteriostat," benzyl alcohol, which is the actual solvent, but which is so soluble in water that the progesterone crystallizes immediately after intramuscular injection. (I have previously written about the history of medical progesterone, and the fraudulent claims and doctrines that have shaped its use.)

Although my observations show that progesterone is much more effective in treating many kinds of cancer than most of the published literature indicates, journal editors "know" otherwise. When I applied for the patent on the formulation of progesterone in vitamin E, the patent examiner told me that I must remove any mention of cancer if I wanted my application to be approved. The "evil mutant cell" theory of cancer, and the official description of progesterone as a "gestational hormone" or progestin, combine to create an attitude that doesn't want to think very long about progesterone's general regulatory functions in the organism.

Synthetic "progestins" have some of the properties of progesterone, and many studies have shown that they can be curative when used against several kinds of cancer. But the prevailing cancer culture has led to their use in combination with cytotoxic chemicals, and/or radiation, rather than with the factors that would really synergize with their "progestational" actions: The factors that would correct the formative, organismic field.

Since part of progesterone's therapeutic action is its ability to raise the concentration of carbon dioxide in the tissues, other techniques that increase carbon dioxide should be used at the same time. Thyroid's action is crucial for the production of carbon dioxide, and for the avoidance of lactic acidosis, adrenalin excess, and other processes that lower carbon dioxide concentration. (And, of course, thyroid is essential for the synthesis of progesterone, and for restraining the synthesis of estrogen, and accelerating its elimination from the body.)

Progesterone, thyroid, and carbon dioxide all protect against the cancer-promoting actions of calcium, and they do this by increasing respiratory energy, which favors intracellular magnesium over calcium. Adequate magnesium in the diet is extremely important. It is counterproductive to eat a calcium-deficient diet, since that tends to increase the intracellular calcium at the expense of calcium taken from the bones.

The immense power of the pharmaceutical industry, and its controlled government agencies, creates a situation in which the work of people like Lipschutz and Needham is written out of the culture. With the loss of a meaningful context, individuals with an authoritarian inclination will believe that science consists of comparing the latest therapeutic products or technologies with the earlier products or technologies. Some of the newer products and technologies will be sold as "alternative medicine," by a different branch of industry. But if the newer alternatives still conform to the view of cancer and life that was created to sell the old products, they can never make a real difference.

Cadherins are major cell-cell adhesion molecules in both tumor and normal tissues. Although serum levels of soluble E-cadherin have been shown to be higher in the cancer patients than in healthy volunteers, the detail mechanism regulating release of soluble E-cadherin remains to be elucidated. Here we show that the ectodomain of E-cadherin is proteolytically cleaved from some cancer cells by a membrane-bound metalloprotease to yield soluble form, and the residual membrane-tethered cleavage product is subsequently degraded by intracellular proteolytic pathway. Futhermore, we show that extracellular calcium influx, that is induced by mechanical scraping of cells or ionomycin treatment, enhances the metalloprotease-mediated E-cadherin cleavage and the subsequent degradation of the cytoplasmic domain. Immunocytochemical analysis demonstrates that the sequential proteolysis of E-cadherin triggered by the calcium influx results in translocation of beta-catenin from the cell-cell contacts to cytoplasm. Our data suggest that calcium influx-induced proteolysis of E-cadherin not only disrupts the cell-cell adhesion but also activates beta-catenin-mediated intracellular signaling pathway, potentially leading to alterations in motility and proliferation activity of cells.

Pathological Science & General Electric: Threatening the paradigm

Everything in biology depends on the internal order of cells, and on the interactions of each cell with its surroundings. All of these orderly interactions involve contacts between biological molecules and water. The forces regulating interactions on that scale must be understood before life can be understood, but the nature of the forces at these interfaces has been controversial for 100 years.

In 1953, physicist Irving Langmuir gave a talk at the General Electric laboratory about what he called "pathological science." That talk is still resonating in the scientific culture, and it is used to reinforce attitudes similar to those held by Langmuir, i.e., the dominant scientific paradigm of the 20th century, and to justify certain institutions that regulate innovation.

For Langmuir, there was a clearly defined "scientific method," and he said some people were led away from the proper method by wishful thinking to interpret ambiguous results as confirmations of their hypothesis. He listed 6 symptoms of pathological science: 1) An effect produced by a barely detectable cause, and 2) the effect is barely detectable, or many measurements are needed because of the very low statistical significance of the results, 3) claims of great accuracy, 4) they involve fantastic theories contrary to experience, 5) criticisms are met by *ad hoc* excuses, and 6) the ratio of supporters to critics approaches 50%, then fades toward zero. He failed to mention these features in any research that supported his view of things, and called an idea pathological when people continued to work on it despite disapproval by the recognized experts. He didn't mention the Nobel prizes that were given for the worm theory of cancer or for treating psychological problems with lobotomies, and he didn't mention that there were organized campaigns against the publication of disapproved ideas.

The dominant view in biology, which is analogous to Langmuir's view in physics, is that all decisive cellular processes involve the direct mechanical contact of one molecule with another, the activation of a lock (an enzyme or receptor) by a key that has the right shape, or the adhesion of a molecule to another substance according to its chemical composition. An alternative view, now clearly supported by the evidence, is that there are forces that aren't merely between molecular surfaces, but rather that the local conditions at the surfaces of proteins and other molecules, and the properties of the solvent water, are modified by the surrounding conditions. It is this alternative view that is now making progress in understanding disease and health, regeneration and degeneration. But to judge the new work, it's important to know the nature of the opposition.

Thomas Edison, who was adept at publicizing himself as the inventor of ideas he had bought or stolen, founded General Electric. Attempting to eliminate Nikola Tesla's system of alternating current, since Edison was invested in direct current systems, Edison's GE tried to convince the public that direct current was safer, by using alternating current to electrocute an elephant, and by promoting its use in the electric chair. GE eventually gave up the direct current technology for electrifying cities, and they refined the electric light bulb and were fairly successful in controlling, practically monopolizing, that market, and in shortening the life of incandescent bulbs. Carbon filament bulbs made around 1900 often lasted decades; I had one that kept working until it was broken during a move in 1960. Light bulbs made in England 65 years ago, and in the Soviet

Union, and bulbs currently made in China, had a life expectancy five times as long as the bulbs made in the US since GE learned how to carefully control the rate at which the tungsten filament deteriorates.

Irving Langmuir was their leading light bulb scientist. In his 1932 Nobel lecture, he tediously argued that molecules of gas can form only one layer on a surface such as a filament. About 17 years earlier, Michael Polanyi had demonstrated that molecules can be adsorbed in multilayers, but his evidence was dismissed because, according to the understanding of industrial experts such as Langmuir, and the leading scientific authorities, Einstein, Nernst, and Haber, it was impossible. They were committed to an explanatory system that didn't allow events such as those Polanyi described.

Although Polanyi knew that his adsorption isotherm was more realistic than Langmuir's (he had demonstrated many cases that Langmuir's didn't describe correctly), and also easier to understand, he taught Langmuir's isotherm to his students, because he knew that they would be required to know it to pass their examinations. He knew he had risked his career by his earlier exposition of his ideas, and he was unwilling to endanger his students' careers by involving them in the controversy.

From 1920 to 1926, before the advent in 1927 of "quantum physics" (with its still-argued features of delocalized electrons, molecular orbitals, resonance, non-locality, incommensurability, indeterminism), Polanyi had turned his attention from the physics of adsorption to chemical structure, and his group was the first to show that cellulose was made up of long molecules, polymers, rather than of just associated clusters. That idea didn't catch on, so he turned to the behavior of crystals and metals. He found that crystals were much weaker than they should be, according to the strength of the bonds between their atoms, and showed that this was because of defects, and that during repeated stresses, they became weaker, as energy migrated through relatively long distances in the substance, to concentrate the defects. The idea of lattice defects was acceptable at that time, but long-range mobility of bond energy was no more acceptable then than it had been when J.C. Bose described metal fatigue, decades earlier.

Polanyi also showed that the strength and rigidity of a crystal were altered when the crystal was immersed in water. Again, such an influence of a surface on the over-all physical properties of a solid substance had no noticeable effect on the scientific culture, although his results were published in the major journals. To adjust one's interpretive system at that time to rationalize Polanyi's results would have required discarding the basic assumptions that were behind Einstein's explanation of the photoelectric effect, and maybe even his theory of Brownian motion. However, by 2011, fewer people have invested their personal development in those ideas of short-range electrical binding forces that prevailed early in the 20th century, and now, for example, the evidence of "delocalized holes in DNA" can be discussed more openly. Eventually, science textbooks may be rewritten to show a steady progression of understanding from Bose, though Polanyi, Perutz, Szent-Gyorgyi, Ling, and Damadian (inventor of the MRI, holder of the patents infringed by GE, non-winner of the Nobel prize).

In 1933 J.D. Bernal had proposed a structural model of water that contained a considerable amount of order (Bernal and Fowler, 1933) but by the 1950s the idea of spontaneous ordering in water was out of style, and he worked out a more random structure. Max Perutz, continuing the study of hemoglobin he had begun with Bernal, became concerned with long range forces acting through water: "The nature of the forces which keep particles parallel and equidistant across such great thicknesses of water is not yet clear." Normal wet crystals of methemoglobin contain regular layers of water 15 Angstroms thick. He suggested that a laminated structure of the water could plausibly explain his measurements. Comparing the protein crystal to montmorillonite particles, which incorporate several layers of water, each 3 Angstroms thick, each layer of water in the protein crystal would be 4 Angstroms thick, since swelling proceeds in discrete steps of that thickness. 52.4% of the volume of Perutz's normal, stable, wet protein crystals consisted of

liquid. Part of the water is a fixed monolayer, but the rest is apparently in the form of mobile, interactive, multilayers. By 1952, Perutz had decided that long range forces weren't involved in hemoglobin crystallization, but he didn't comment on the long range ordering of clays, tobacco mosaic viruses, and other particles and gels. In 2005, an interlaminar distance of 17.9 Angstroms, or six layers of water, still seems to be stable in hydrated montmorillonite (Odriozola & Aguilar, 2005). Clay continues to be studied in relation to nuclear waste disposal, so the effects of surfaces on water's properties haven't been entirely excluded from science. The interfacial water in clay has special catalytic properties that make it interesting to many researchers (Anderson, 1970)

Bernal's and Perutz' conformity to the 1950s rejection of long range forces and an ordered structure of water represented the dominant ideas in physics and physical chemistry, but many people (with very little financial or institutional support) were continuing to study the structure of water, both in the bulk phase and near surfaces, as in cells. Philippa Wiggins, Albert Szent-Gyorgyi, Carlton Hazlewood, Freeman Cope, and Ray Damadian were among the most active proponents of the importance of structured water in living cells. Walter Drost-Hansen showed that water near surfaces (vicinal water) is several percent less dense, and has a greater heat capacity, than bulk water, and that bulk water undergoes transitions at certain temperatures that alter its effects on enzyme reactions.

The question regarding the nature of the forces at surfaces or interfaces affects how we think about everything, from life to nuclear energy. The political and economic implications of "non-local energy" (which is most obvious at surfaces) have at times led to organized campaigns to discourage research in those areas. When Alexandre Rothen found (beginning in 1946) that enzymes and antibodies had non-local effects, several prestigious publications claimed to show how he must have been mistaken: The films he used must have been porous, despite his demonstrations of their continuity.

The methods he developed at Rockefeller Institute quickly became standard for accurately measuring very thin films. In the early 1970s, a GE employee, Ivar Giaever, visited Rothen's lab to learn his methods. Shortly after his visit, he demonstrated his "new method" to the press. I saw an article about it in Science News, and wrote them a short letter, pointing out that the method had been developed and used by Rothen much earlier; they printed my note, which could be seen as a criticism of the author of the news article. About a week later, I got a letter from Rothen, thanking me for writing to the magazine; he said they had refused to publish his own letter explaining the situation, including his interactions with Giaever during the visit. I assume that the magazine felt some kind of pressure to protect Giaever and GE from an authoritative accusation of scientific dishonesty.

In 1968 when I began studying biology at the University of Oregon, the professor of microscopy, Andrew Bajer, posted a display of dozens of micrographs, with explanatory captions, along the halls near the entrance of one of the science buildings. The one that interested me most showed orderly rows of regularly formed objects on a smooth surface. The caption described it as clusters of sodium atoms, deposited from vapor, on a film of a polymer (formvar, I think), under which was a quartz crystal. The caption noted that the sodium atoms had condensed in a pattern representing the crystal structure of the underlying quartz. Although Rothen's work involved proteins deposited from solution, rather than sodium atoms deposited from vapor, Bajer's image illustrated visually the projection of the forces of crystal structure through an amorphous film. This seemed to be a graphic representation of Polanyi's adsorption potential, a force acting on atoms in the space near a surface, as opposed to Langmuir's local atomic force that didn't reach beyond the first layer of atoms. The long range order in this case arranged atoms geometrically, while Rothen's preparations showed a "projected" specificity, but of a more complex sort.

Just a few months later, someone who knew of Stephen Carter's demonstration that fibroblasts will migrate on a glass slide coated with a gold

film, toward areas of greater thickness of the metal, did a similar experiment, but with a formvar film between the gold and the cells. The cells still migrated up the gradient, toward the area of thicker gold under the film. The reaction to that publication was the same as the reaction to Rothen's work 20 years before, the formvar films contained holes, and the cells were reaching through the film to touch the metal surface, sort of like kids peeking around a blindfold when they aren't supposed to be watching. I didn't understand how the holes would explain anything, even if there were holes and if the cells had put out many long filopodia to reach through the film, but in fact making a formvar film is a very standardized technique. They can be made "holey," or like a very open net, or they can be made solid, just by choosing the concentration of the polymer used. The difference is very clear, under an electron microscope, but the professors needed an excuse for dismissing something they didn't want to understand. Further work was discouraged by their ridicule.

In Russia, GE had very little influence on the acceptability of ideas in science, and Boris Deryagin continued (from the 1930s until 1990) to study the properties of water near surfaces. In 1987 his group demonstrated that cells can clear particles from a space around themselves, extending more than a cell's diameter away. This distance is similar to the cell free zone in flowing blood adjacent to the walls of arterioles, which is probably the result of multiple interacting forces. At present, processes such as cell adhesion of leukocytes and stem cells (and tumor cells) to the blood vessel wall and movement through the blood vessel into the tissues (diapedesis) is explained in terms of adhesion molecules, disregarding the plausible effects of long range attractive or repulsive forces. Clumping or sludging of red blood cells occurs when the organism is failing to adapt to stress, and could be reasonably explained by a failure of protective repulsive fields. These fields are developed and maintained by metabolism, primarily oxidative energy metabolism, and are modified by endogenous regulatory substances and external conditions, including electromagnetic and electrical fields.

100 years ago, Albert Einstein was a major influence in popularizing the "only local" dogma of atomic interactions. (His work led directly to "quantum physics," but he never accepted its irrational implications.[1] I don't think he ever considered that the assumptions in his [atomic-quantized] theory of the photoelectric effect were the problem.) One charged atom is completely neutralized by its association with an oppositely charged atom, and the force is described by the inverse square law, that the force decreases with the square of the distance between point charges, meaning that the force is very strong at very small distances. However, a physical ***surface***, a plane where one substance ends and another begins, follows different rules.

Different substances have different electron affinities, creating a phase boundary potential, a charged layer at the interface. (Electrical double layers at interfaces are important in semiconductors and electrodes, but biologists have carefully avoided discussing them, except in the very narrow context of electrodes.) The electrically active surface of a substance, even though it's made of atoms and electrons, projects its electrical field in proportion to its area. This principle is as old as Coulomb's law, but the habit of thinking of electrical charge on the atomic scale seems to make people forget it. It's exactly the sort of space-filling field that Polanyi's adsorption isotherm describes. It's also involved in crystal strength and elasticity as studied by Polanyi, in piezoelectricity, and in generation of semiconduction in amorphous materials, as used in Stan Ovshinsky's processes.

Long range structural and electronic interactions produce "antenna" effects, which are sensitive to very weak fields, whether they originate inside or outside of the organism. Magnetobiology is often treated as a pseudo-science or pathological science, because "real science" considers heating and chemical bond reactions to be the only possible effects of low energy fields or radiation. Solco Tromp, beginning in the 1930s, showed that cells behave like liquid crystals, and that liquid crystals can respond to very low electrical and magnetic fields.

If the adsorption potential structures the water in its region of space, this interfacial water is now a new *phase*, with different physical properties, including new catalytic properties, such as those recognized by the clay investigators (which increased its ability to dissolve the clay minerals).

Several versions of Langmuir's Pathological Science talk have been published, some of them adding new examples, including "polywater." Langmuir died in 1957, and the first example of polywater was observed by N.N. Fedyakin was observed in 1961. When finely drawn quartz or Pyrex glass capillary tubes (with inside diameter of up to a tenth of a millimeter) are suspended in a container with the air pressure reduced, above a container of distilled water, so that they are exposed to pure water vapor at room temperature, after a period of an hour or more (sometimes days or weeks were required) a small drop of liquid condenses inside some (a small percentage) of the capillary tubes. Above some of the original drops, a second drop sometimes appeared, that would enlarge as the first drop shrank. This separation of water into two fractions was itself anomalous, and the upper drop was found to be denser than normal water. Many people began studying its properties. Fedyakin found that its thermal expansion was greater, and its vapor pressure lower, than ordinary water. Others found that it had a higher refractive index, viscosity, and surface tension, as well as greater density, than ordinary water. Birefringence (the splitting of a beam of light into two rays when it passes through an ordered material) was observed in the anomalous water, and this usually indicates the presence of a polymer (Fedyakin, et al., 1965; Willis et al., 1969; Lippincott, et al., 1969) or crystallinity. The water associated with clay is also birefringent (Derjaguin and Greene-Kelly, 1964), and its properties are different when the clay absorbs it from the vapor phase or from liquid water.

Hysteresis is a lag in the behavior of a system, resulting when the internal state of the system is altered by an action, so that it responds differently to a repetition of that action; it's the memory of a system that exists only when the system has internal structure. For example, a gas has relatively little hysteresis. Perfect elasticity is one extreme of an ordered solid, but most solids have some hysteresis, in which the deformed material fails to spring back immediately. Hysteresis of adsorption can be seen at the edges of a drop of water on a tilted surface, with a steeper contact angle on the newer contact at the lower edge, showing a reluctance of the water to wet a new surface, a lower contact angle where the drop is pulling away from the upper surface, a reluctance to break the contact. The same is seen at the edges of an evaporating-shrinking drop, or a growing drop. Everyone perceives this memory function of water.

Boris Deryagin studied both the elasticity and the hysteresis of water near surfaces, and both approaches showed that it contained internal structure. Many dogmatic professors denied that water could show elasticity or "memory," because of their interpretive system/mental rigidity.

When Fedyakin got the help of Deryagin's lab in analyzing the anomalous material, many different methods of purifying the glass and the water and the vessel were tried, and its properties were analyzed in many different ways. When Deryagin first described the material at a conference in Europe, there was great interest, and eventually hundreds of people began investigating it.

A British laboratory was the first to get a sample of Deryagin's material in 1966, and their tests confirmed Deryagin's.

The US Bureau of Standards, having the best analytical instruments in the world (including a microscope spectrometer), studied it carefully. They (Lippincott, Stromberg, Grant, & Cessac, 1969) found that its bonds were stronger than those in ordinary water, and they compared its absorption spectrum (by computer) with those of 100,000 known substances, and found that it corresponded with nothing previously known. It didn't have the absorption band of normal water. When it evaporated, it left no visible residue, and it turned into ordinary water when heated. They concluded that the physical structure that would best fit its absorption spectrum was a polymerized form of water, so they called it "polywater." Later, Lippincott and others (Page, et al., 1970; Petsko, 1970) did proton magnetic resonance analyses that

showed a difference of polywater from normal water in the hydrogen bonding, a "deshielding" of the protons, meaning that the electrons were arranged differently in the molecules.

In 1969 there were many threats to the dominant paradigm, and many people were demanding a change in the government's funding priorities. The public excitement about polywater following the many confirmations of its existence was disturbing to the defenders of the paradigm. Philip Abelson, the chief editor of Science magazine, used the magazine to further his political beliefs.

Denis Rousseau, a young researcher at Bell Labs (who now writes about pathological science), published a series of articles in Science describing his tests of polywater. He played tennis until his tee-shirt was soaked with sweat, then extracted and concentrated the sweat into a small gummy pellet. He reported that the infrared spectrum of the sweat concentrate (largely sodium lactate) was very similar to that of polywater. One of the techniques he used to identify impurities (electron spectroscopy) requires a high vacuum, so there couldn't be any normal water present. The water associated with ionic impurities is driven off at low temperatures compared to the temperature needed to decompose the anomalous water.

Although Rousseau's "explanation" was ludicrous, it was just the thing the professors needed to prevent further challenges to their paradigm. Although Deryagin published more evidence of the purity of the anomalous water in 1972, by 1973 the mass media, including Science magazine, were saying that polywater didn't exist, and that Deryagin had admitted that he was mistaken. But polywater was Lippincott's term, and what Deryagin said was that silica was the only impurity that could be identified in the anomalous material.

There are many antecedents to anomalous water in the literature. In the 1920s, W.A. Patrick of Johns Hopkins and J. L. Shereshefsky at Howard university investigated the properties of water in fine capillary tubes and found that the vapor pressure wasn't the same as that of normal water. (This is what would have been expected, if Polanyi's adsorption isotherm had been accepted.) The density of water in clay has been found to be slightly less than normal. This water bound to clay requires a high temperature to eliminate, similar to the decomposition temperature of polywater. The catalytic properties of interfacial water in clay are recognized, causing it to solublize components of the clay. So it's hard to imagine that there wouldn't be some silica in the material formed in quartz or glass capillary tubes.

The only thing pathological about the polywater episode was the extreme effort that was made to stigmatize a whole category of research, to restore faith in the old doctrine that insisted there are no long range ordering processes anywhere in the universe. The successful campaign against polywater strengthened the mainstream denial of the evidence of ordering in interfacial and intracellular water, kept the doctrine of the lipid bilayer cell membrane alive, and up until the present has prevented the proper use of MRI scans in medical diagnosis.

In 1946, while the government was studying the way nuclear fallout was influenced by the weather, a group at GE, led by Langmuir, began experimenting with weather control by means of "cloud seeding." Langmuir observed that the energy in a cloud system was greater than that in an atomic bomb, and that by seeding clouds in Europe, disastrous weather effects could be created in the Soviet Union. The GE group convinced the Pentagon to become involved in weather control. (The physicist Ross Gunn was transferred directly from work on the atomic bomb to direct the cloud seeding project.) In one of Langmuir's seeding experiments, he claimed that he had changed the direction of a hurricane moving toward the U.S. When a young researcher pointed out that the weather service had predicted exactly that change of direction, based on the temperatures of ocean currents, Langmuir became angry, and told the man that he wasn't going to explain it to him, because he was too stupid to understand.

Langmuir's attitude toward science was exactly what GE wanted; his career and reputation were part of the corporation's public relations and business plan. Science was whatever GE thought

was good for their business. That science was pathological, sometimes by Langmuir's own defining features, most of the time by the effects it has had on society. The Manhattan Project was central to GE's business plan, and when the bomb project was completed GE and the Atomic Energy Commission found that the same subsidies could be used to develop nuclear generators of electricity. Following Edison's pioneering work with x-rays, x-ray imaging machines had become very profitable for GE. It was important to assure the public that medical, industrial, and military radiation was well understood, well controlled, safe, and essential for the general welfare. In their view, if every woman could have access to GE's x-ray mammograms, for example, almost all breast cancers could be cured. The radiation exposure from living near a GE nuclear power generator is infinitesimal compared to living in Denver or flying in an airplane. (There is some discussion of these issues in my January, 2011 newsletter, "Radiation and growth.") Public relations involves everything from "basic research" to television advertising.

If nuclear energy is as safe as the industry and governments say it is, the reactors should be located in the centers of large cities, because transmitting electric power long distances is presently wasting 50% of the power (Hirose Takashi, The Nuclear Disaster that could destroy Japan...and the world, 2011). Admiral Rickover, influential advocate of nuclear power, said "...every time you produce radiation, [a] horrible force [is unleashed,] and I think there the human race is going to wreck itself. [We must] outlaw nuclear reactors" (January, 1982 congressional testimony) Helen Caldicott says Fukushima is many times worse than Chernobyl. The radioactive cesium in German mushrooms and truffles hasn't decreased 25 years after Chernobyl, and the German government is spending increasing amounts to compensate hunters for the wild boars (who eat truffles) that must be disposed of as radioactive waste.[2]

General Electric sent its condolences to the people of Japan, and said the reactors of that design had functioned well for 40 years; they didn't mention that Unit I at Fukushima had been scheduled to be shut down on March 26, 2011, the end of its 40 year life expectancy. In late March, as the accident continued, Tepco applied for a permit to build two new reactors at the Fukushima site. In the US, the government continues its loan guarantee policy to subsidize new reactor construction.

After many years of working with his metalized slides, Alexandre Rothen found that their activity, the strength of their long-range influence, varied with a 24 hour cycle, and that their activity could also be destroyed or restored by putting them in a magnetic field, parallel or perpendicular to the surface. Around the same time, a Russian biochemist, Simon Shnoll, noticed that there were cyclic changes in well defined enzymic reactions. Like Rothen, Shnoll did experiments that showed that the earth's motion (relative to the stars) affected measurements in the laboratory, even measurements of alpha particles produced by nuclear fission. Organized matter, whether it's cellular or in the crystalline solid state, is susceptible to surrounding conditions.

In 1971 or '72 I learned of H.C. Dudley's idea of a "neutrino sea," that he suggested might be equivalent to the "luminiferous ether" that had previously been used to explain light and electromagnetism. I wrote to him, asking if he thought neutrinos could be involved in biological ordering processes by resonating with matter under some circumstances. He had been developing a theory, in which atomic nuclei might interact with a neutrino "ether," in ways that could affect the decay rate of the unstable isotopes, and so it didn't seem unreasonable to him that biological structures might also interact with neutrinos. In October, 1972, he published a purely theoretical article in which he explained that nuclear reactors might under some conditions become dangerously unstable. I had earlier seen a newspaper article about an experiment by a physicist, J.L. Anderson, in which radioactive carbon-14 didn't follow the normal rules of random decay, when the isotope was incorporated into an oil, which was spread in a monolayer on a metal surface. By chance, Anderson's experimental article was published simultaneously with Dudley's theoretical article, though neither one knew of the other's work.

Nearly all physicists said his results weren't possible, because the small forces involved in adsorbing an oil to a metal surface were infinitesimal compared to the force needed to cause nuclear reactions. Over the next few years, Dudley and others did some experiments that appeared to confirm Anderson's results, showing that the rate of nuclear reactions can be modified by mild changes in the physical state of the unstable elements.

Anderson's and Dudley's work didn't get much attention from the public, so there was no need for the defenders of the dominant paradigm to attack it. There was no financial support for continuing their research.

Behind the industries' assurances that "low level" radiation is safe, whether it's ionizing radiation, microwave or broadcast frequency electromagnetic radiation, is their reductionist approach to physics, chemistry, and biology. Those doctrines no longer have the prestige that they once did, but their pathological, authoritarian "science" culture is being sustained by the influence of corporations on mass culture.

With the institutions of research and education controlled by pharmaceutical, military and industrial interests for their own benefit, fundamental progress in knowledge is a threat to the system.

NOTES

1. From Einstein's 1926 letter to Max Born: "Quantum mechanics is very worthy of regard. But an inner voice tells me that this is not yet the right track. The theory yields much, but it hardly brings us closer to the Old One's secrets. I, in any case, am convinced the He does not play dice." Quoted in P. Busch and G. Jaeger, "Unsharp quantum reality," 4 May 2010.

2. None of the major institutions in the US are providing basic information about protection from Fukushima's radioactive fallout. Eating foods produced before the arrival of the radioactive rain, feeding old foods to chickens and milk animals, and keeping your metabolic rate high, are the main defenses. Eventually, fertilizing crops with mined minerals, and enriching the atmosphere with carbon from coal will dilute the radioactive isotopes from the nuclear accidents.

The GABA system, defenses, and tissue renewal

Inhibition is an active process, that isn't limited to the effects of specific inhibitory nerves. In recent decades, the amino acids gamma-aminobutyric acid (GABA) and glycine (alpha-aminoacetic acid) have been identified as "inhibitory transmitters," acting on specific receptor proteins to inhibit a nerve or muscle.

This has led to increasing understanding of some sedative and anti-convulsive drugs, but it neglects the real biological nature of inhibition and excitation. The amino acid "transmitters" are just part of a much larger system of cell regulation.

To understand healing and regeneration and other developmental and formative processes I think it's necessary to consider the issues of cellular and organismic stability and instability, inhibition and excitation, in the most thorough and general way.

Cell interactions generally involve mutual stabilization. Nerves stabilize muscles, muscles stabilize nerves, and nerves stabilize other nerves. Losing their normal intercellular communications, cells become hypersensitive and hyperactive.

When an excess of stimulation threatens to damage a tissue, processes of inhibition can restore stability. But when cells are damaged irreparably, stimulation can induce other cells to grow and multiply to replace the lost cells. The growth continues until inhibitory processes are restored.

Protective inhibition is one of the most important principles in biology. Heart disease, cancer, anxiety, allergies, epilepsy, degenerative nerve diseases, endocrine disorders, inappropriate inflammation and shock all involve defects of protective inhibition.

The agents of protective inhibition increase survival, along with mental abilities and metabolic rate. Too often the excitants suppress energy production while increasing the need for energy, leading to impaired functions and failure of restorative processes.

For thousands of years people have understood the value of herbal sedatives, soporifics, and anti-convulsants, but modern neurology's ideological commitments have retarded the scientific development of therapies to enhance protective inhibition.

J.C. Bose, working in England and India at the end of the 19th century (radio, microwave, vegetable electricity, the electric response of inorganic substances), showed that plant cells and animal cells have very similar reactions, and that similar processes of excitation, fatigue, and recovery also occur in substances such as metal. Drugs and poisons could be shown to have effects on plant material and metals,* analogous to their effects on animals.

Michael Polanyi's work with crystals in the 1920s showed that merely wetting a surface affected the physical properties of the whole crystal.

His understanding of sensitivity, irritability, fatigue, memory and other biological processes disturbed the academic biologists, who were committed to a certain biological doctrine in which membrane electricity and genes explained everything, and had nothing directly to do with general properties of matter.

C.S. Sherrington in England, and S. Ramón y Cajal and R. Lorente de Nó in Spain developed the idea of the synapse as a point of interaction between nerve cells, which formed the basis for reflexes. A nerve would transmit its excitation to a muscle or another nerve in an all-or-none manner, that is, the reaction, if it happened at all, didn't correspond to the strength of the stimulation. The reductionist ideology was already, at the beginning of the 20th century, reducing biological interactions to simple yes or no, black or white, terms. The infinite complexity of the material substrate was eliminated from direct participation in the scheme of life by definition.

Like Descartes, Sherrington and his followers saw reflexes as something separate from consciousness. "Between reflex [automatic] action and mind there seems to be actual opposition. Reflex action and mind seem almost mutually exclusive - the more reflex the reflex, the less does mind accompany it." "The mental action lies buried in the brain, and in that part most deeply recessed from outside world that is furthest from input and output."

Later in the 20th century, biologists were still identifying consciousness with graded processes, that are too subtle to be accounted for by the all-or-none synaptic interactions of nerves.

In 1863, I.M. Sechenov had already published a book, Reflexes of the Brain, arguing that all aspects of the mind, including thoughts and feelings, directly involve nervous activity.

A Russian biologist, Vvedensky (1902), demonstrated that weak stimuli and strong stimuli applied to a nerve produced very different effects in the muscle activated by the nerve. "Wedensky *[German spelling]* found that at a certain stage in the fatigue or narcosis of a muscle-nerve preparation, a series of strong or rapidly recurring stimuli may produce a small initial contraction only (Anfangszuckung), whereas a series of weak or slowly recurring stimuli produce a continued tetanus." (J Physiol. 1913 July 18; 46(4-5): 384-412. Wedensky inhibition in relation to the `all-or-none' principle in nerve. E. D. Adrian.)

Another Russian biologist, P.N. Nasonov, using a variety of cell types, including algae, showed that an excessive stimulation that weakened a cell's ability to respond electrically also weakened its resistance to other environmental factors, and that the right kind of stimulation could increase the cells' resistance to stress. These ideas were expanded and applied to human health issues by the cardiologist F.Z. Meerson, whose laboratory investigated the protective and therapeutic effects of the complex multi-level inhibitory anti-stress system.

The Sherrington tradition, the synapse-membrane all-or-none school of neurology, was complemented by the hormone-receptor-gene-activation school of endocrinology, and by parallel reductionist approaches to embryology. None of these traditions produced anything useful, except in the sense that the receptor doctrine was perfectly suited to pharmaceutical advertising.

The all-or-nothing reflex doctrine reinforced an interpretation of the cell in which a barrier membrane at the cell surface momentarily opens when it's appropriately stimulated, allowing excluded sodium ions to enter, modifying the electrical field and causing a reaction that "propagates along the

nerve like a line of falling dominoes." As Gilbert Ling has pointed out, that doctrine isn't based on real science--for example, the resting membrane doesn't exclude sodium ions. Many things account for the fact that it continues to be taught, but I have talked about that previously. The fact that "membrane depolarization" makes it easy to conceptualize propagation of the excited state as an all-or-none process appeals to the reductionist mentality. But more than 70 years ago, A.V. Hill's measurements of heat production during nerve activity demonstrated that the wave of excitation passes through the entire substance of a nerve, rather than being a matter of "falling dominoes" in the superficial plasma membrane.

It is in the substance of the nerve cytoplasm itself that the protective inhibitory processes occur. In the all-or-none membrane theory in which reflexes are produced by synaptic events, the inhibitory GABA receptors are described as membrane receptors. The basic theory of membrane receptors is that, since the membrane is a barrier, the receptor allows hormones or transmitter molecules to act on the cell without having to enter the cell.

But when a molecule resembling an inhibitory steroid was made water soluble, so that it couldn't enter cells, it was unable to activate the GABA receptor associated with the membrane. When it was presented to the receptor from the cytoplasmic side, however, it was able to modify the GABA receptor. (Akk, et al., 2005.) The normal oil soluble neurosteroids tend to remain in the cells when they are made there, or to enter them spontaneously from the bloodstream, so the postulated function of "membrane receptors" would seem to be wrong. The GABA receptor has been found to associate with the internal cytoskeletal proteins. This is significant, because the glutamate transporter, that participates in restoring inhibition, has recently been found to be associated with a cytoskeletal protein (GFAP) (Sullivan, et al., 2007). This protein is known to be induced by progesterone.

The membrane theory is an attempt to explain the coordination of events that happen in a cell when it is stimulated. The different phases of heat change observed by Hill and others subsequently can only be explained as a phase change in the bulk of the cellular substance, not just a ripple in a superficial lipid film. Different molecular conformations and associations have different levels of organization, that represent structural energy, and different arrangements are separated by small energy barriers. Mutual stabilization of molecular systems gives way to a cooperative phase transition and the establishment of a new organization at a slightly different energy level when stimulation overcomes the energy barrier. The domino analogy is inadequate because the change is three dimensional. Proteins, lipids, sugars, water and ions participate in these cooperative structural changes.

A student of Pavlov's, P.K. Anokhin, discussed a variety of reasons for believing that the information transmitted by the activated state of an axon was complex, rather than a single binomial bit. Since his time many kinds of information have supported and enriched that view. Cellular interactions are always complex, and the all-or-none reflex is an extremely misleading abstraction.

Drugs and natural regulatory substances associate with certain proteins, and those proteins are identified as their "receptors." Since the technique of "knocking-out" the genes for specific receptors has been developed, it has become apparent that the regulatory substances are often able to act without the protein that had been known as the receptor. (For example, Reddy and Apanites, 2005.) Other proteins may then be identified as additional receptors. Occasionally, the

condition of the phospholipids and fatty acids, or the preceding state of the cell, is recognized as having a crucial role in the cell's response. But this holistic view hasn't been useful to the pharmaceutical industry.

Interacting cells are participating in a developmental process, in which their structures and metabolisms are regulating themselves in relation to their situation, which is influenced by events in the life of the whole organism. An organism's anticipation and learning contribute to the renewal of tissues and resistance to stress. Unavoidable stress damages or kills nerve cells, and the resulting mobilization of defenses can lead either to successful defense and recovery, or inadequate defense and chronic disease.

Once the protective function of inhibition is recognized, there are many things that can be done to support the organism's recuperative processes.

Pavlov and his followers began applying the principle of protective inhibition to medicine, and it has been used to treat neuroses, brain injuries (even "brain death"), and various organic diseases. Pavlov observed that individual differences in nervous stability could cause the therapeutic dose of a sedative to vary several-fold. Prolonged sleep was found to be a very powerful therapy, that could even reverse age-related changes, but drugs such as the barbiturates were too toxic for extensive use of the therapy. Sleep induction by electrical brain stimulation was investigated as an alternative. Subsequently, Meerson's group investigated the metabolic and biochemical factors involved in protective inhibition. Although Meerson's research focused on the heart, the factors he identified apply to other organs and tissues. The progressive commercialization of medical research, however, has submerged those integrated organismic approaches to therapy.

Using the general approach of Pavlov and Meerson, it's now possible to achieve a high degree of protective inhibition without using toxic drugs, but it's important to minimize the chronic factors that create a susceptibility to uncontrolled excitatory states.

The toxic effects of excessive stimulation involve suppression of respiratory energy production. Excitation releases fatty acids from tissue phospholipids, and the polyunsaturated fatty acids (PUFA) increase excitation, decrease the inhibitory actions of the GABA system, and interfere with energy production by the mitochondria, leading to the wasteful conversion of glucose to lactic acid. Excitation increases the production of free radicals by the mitochondria themselves (Duan, et al., 2007). Just eliminating most PUFA from the diet decreases the risks of excitotoxicity.

DHA and arachidonic acid increase the excitatory effect of glutamate on its receptor (Yeh, et al., 1995), and decrease the uptake of glutamate by the protein that binds it to stop the excitatory process (Yu, et al., 1986). These fats cause swelling of mitochondria and cells, and increase vascular permeability. Saturated fats don't have those excitatory effects.

Fish oils and other omega -3 oils are being promoted as treatment for many diseases, especially heart disease, arthritis and other inflammatory diseases, and depression. They do have an antiinflammatory effect, at least in the short term, partly associated with their inhibition of prostaglandin synthesis, but their antiinflammatory effects have been found to result from their oxidized products (Chaudhary, et al., 2004), which have many toxic effects. Although claims are made regarding their beneficial effect on the circulatory system, there are good reasons to think that they contribute to atherosclerosis (for example, Wang and Oram, 2002, 2005). And they suppress the immune system and thyroid function.

The PUFA (especially the omega -3 fatty acids) spontaneously decompose into a variety of toxins, and arachidonate is also enzymically converted into prostaglandins, some of which exacerbate the excitatory damage (Pepicelli, et al., 2005); aspirin's neuroprotective effect (Riepe, et al., 1997) is probably partly caused by inhibiting prostaglandin synthesis. Besides the prostaglandins, other mediators of inflammation including nitric oxide and interleukins are produced by excessive excitation, as cells lose their ability to retain magnesium, and to control excitatory intracellular calcium.

Nitric oxide, associated with unbalanced excitation, is involved in the nerve damage of epilepsy, amyotrophic lateral sclerosis, Parkinson's disease, Alzheimer's disease, and Huntington's disease. An energy deficit increases excitation and cellular calcium uptake, increasing nitric oxide synthesis (Schulz, et al., 1997). Nitric oxide increases the ratio of glutamate to GABA ("the excitotoxicity index"), (Demchenko & Piantadosi, 2006), while lowering mitochondrial energy production.

The PUFA increase the susceptibility to excessive serotonin in the nervous system. One of the functions of the GABA system is to inhibit serotonergic nerves (Calogero, et al., 1988; Kaura, et al., 2007). Eating a diet with a very low tryptophan content, and lacking PUFA, can support that function of the GABA system. The tea amino acid, theanine, suppresses serotonin by supporting the effects of GABA. Three of the major types of antidepressant also protect against glutamate/aspartate-induced nitric oxide formation and nerve cell damage (Li, et. al., 2006).

It's important not to confuse the process of inhibition with psychological depression, which often involves an inability to inhibit the stress responses. The GABA system restrains the production of cortisol, which is typically increased in depression. GABA-supporting drugs that had been used to treat epilepsy are turning out to have antidepressive, mood-elevating effects.

The diazepam type of antianxiety, antiseizure drug activates the GABA system, and this system is intimately involved with the synthesis of steroids. Several varieties of that type of sedative increase the synthesis of the neurosteroids, derived from progesterone. Progesterone and some of its metabolites protect the mitochondria, while acting with GABA to increase the state of inhibition.

During the menstrual cycle, the GABA system is weaker during estrus, when estrogen's effect is high. Progesterone is associated with a higher level of GABA, and the two substances have many of the same effects on behavior.

Estrogen's excitatory effects can be seen in all types of tissue. In the brain, it tends to increase physical activity and loquacity, to increase the susceptibility to seizures, and sometimes to cause chorea, involuntary random jerking and writhing movements.

It is antagonistic to the GABA system, and promotes the action of excitatory transmitters, and increases formation of nitric oxide and prostaglandins. In cancers that are promoted by estrogen, GABA, like progesterone, inhibits cell division. It is an antiproliferative agent in normal tissues, too, opposing estrogen's effects and supporting progesterone's.

Drugs (such as piracetam) that promote GABA's effects are called "nootropins," or cognitive enhancers, and have been used to treat brain damage and mental retardation. GABAergic agents also protect the thymus gland and improve immune functions.

The first serious approach of the pharmaceutical industry to treating Alzheimer's disease was based on increasing the excitatory action of acetylcholine. When it became apparent that those drugs weren't helpful,

there was a less publicized trial of some drugs that block the effects of acetylcholine. If white doesn't work, they try black. The industry's function, exercised through medical and science journals, and medical schools and universities, is to sell new products, and that has often made it necessary for the industry to suppress approaches that would make their products unnecessary. As the head of a drug company told me, a drug that cures quickly isn't a good drug; a good drug is one that the patient has to keep taking for the rest of his life.

Progesterone's inhibitory function was already well established in the 1940s, by the work of Selye and Lipshutz, for example. In the 1950s and 1960s its effects on brain development and intelligence were established. In vitro studies showed that it was a nerve growth factor, and it was identified as a hormone that caused new brain cells to develop in an area of birds' brains as their ability to sing developed. Katherina Dalton's clinical experience supported the animal work which showed that prenatal exposure to higher levels of progesterone improved mental functioning later in life.

Progesterone supplementation can sometimes cause complete recovery from dementia and motor neuron diseases.

After many years of animal experiments showing that progesterone promotes recovery from traumatic brain damage (Cutler, et al., 2007; Stein, 2007), it is now being used to treat people following severe brain injury (Wright, et al., 2007).

Neither progesterone nor GABA stimulates cell multiplication, yet they improve the regenerative process. Their effects are the result of preventing premature cell death, and promoting normal differentiation and maturation. In various kinds of degenerative brain disease, the connective tissue glial cells in the brain become too numerous, while the nerve cells decline. Excitatory processes cause new cells to be formed, and with the proper energetic and inhibitory support the new cells can mature into functional nerves, that maintain or restore the existing systems and functions.

Certain kinds of excitation cause new nerve cells to be formed (neurogenesis). The enzyme that liberates arachidonic acid (phospholipase A2, which also releases docosahexaenoic acid DHA) from tissue structures, creates a type of phospholipid that is slightly more water-soluble and mobile because of the removal of that fatty acid. These are called lysophospholipids, because they were originally identified as a substance that lysed red blood cells. The enzymes that produce them are activated by many things, including free radicals, increased calcium, and the shift of balance toward excitation (Birkle, 1992), away from dominance of the GABA system.

The lysophospholipids stimulate, among other things, neurogenesis (Fukushima, 2004; Harada, 2004; Ishii, et al., 2003; Dubin, et al., 1999). The arachidonic acid that is liberated in its formation excites cells, in a process that can get out of control if the inhibitory GABA system is weak. It can produce gliosis from excessive stimulation of cell division combined with a lack of the factors such as GABA needed for maturation into nerve cells, and it can kill nerve cells, by interrupting their energy production. The accumulation of this and related fatty acids with aging is a problem.

The DHA and other polyunsaturated fatty acids released by cellular excitation cause mitochondrial damage and edema, but saturated fatty acids don't have those effects (Chan and Fishman, 1980, 1982; Chan, et al., 1988; Hillered and Chan, 1988, 1989).

Alexis Carrel, with a famous experiment begun in 1912, showed that animal tissues kept in culture dishes with frequent (daily)

changes of the growth medium didn't age, and he suggested that changes in the fats in the body accounted for aging. Lately the gene-technology people have said fraud was involved in Carrel's experiments, but many other kinds of experiment produced similar results. For example, Hans Selye found that frequent changes of fluid prevented aging of tissue growing inside an implanted capsule.

Polezhaev's discovery that mammalian tissues can be induced to regenerate by the presence of degenerating tissue (which releases the breakdown products of phospholipids and proteins) is consistent with the recent demonstrations that stem cell growth is activated by fatty acids and phospholipids.

The saturated fats, rather than simply lacking the toxic and excitatory properties of the polyunsaturated fats, are being shown by many types of research to have protective, inhibitory, and restorative actions.

The medium chain triglycerides (MCT, usually made from coconut oil) are easily oxidized by mitochondria, and are often used to produce ketosis, to prevent seizures. A high-fat diet has been used since about 1920 to control epilepsy, but there is no generally accepted explanation for its effect. A ketogenic diet produces acetone, acetoacetate, and beta-hydroxybutyrate ("ketone bodies") and these are protective against seizures (Rho, et al., 2002). Besides providing energy to mitochondria, hydroxybutyrate is structurally close to GABA. Other close analogs, gamma-hydroxybutyrate, gamma-butyrolactone, and 1,4-butanediol, clearly act as regulatory substances, rather than as mere energy sources, though mitochondrial energy supply is an important issue in seizures. Even acetate itself is protective (Urion, et al., 1979).

A feature common to many antiseizure chemicals is a series of saturated carbon atoms, for example valproic acid (2-propylpentanoic), valeric acid (pentanoic acid), dipropylacetic acid, isoleucine (2-amino-3-methylpentanoic acid), leucine (2-amino-4-methylpentanoic acid).

The main difference between metabolism of glucose and metabolism of fat for energy is that fat can't be metabolized into lactic acid, while glucose and fat can both be metabolized to carbon dioxide. When mitochondria are damaged, cells compensate by producing and excreting lactic acid.

Alzheimer's disease has been described as "diabetes of the brain," because the demented brain uses glucose and oxygen very slowly. The easily metabolized medium chain triglycerides can improve mental functions in Alzheimer's patients (Reger, et al., 2004).

Although diabetes is described as an inability to use glucose, diabetics usually have increased lactate in their blood, indicating that glucose is being used wastefully, at the same time that some energy is produced from fat. Mitochondria damaged by chronic exposure to PUFA have a low rate of oxygen use and energy production.

In old age, and sometimes in younger people, mitochondria lose some of their DNA, and are unable to produce the proteins needed for full metabolic activity. In younger people, a type of mitochondrial defect causes seizures and lactic acidosis. The production of lactic acid tends to raise the intracellular pH (especially when carbon dioxide isn't being produced) while it tends to lower the blood's pH. High intracellular pH is excitatory. The "genetically" defective mitochondria can be replaced by genetically normal mitochondria if the ketone bodies are provided (Santra, et al., 2004). A similar restoration of normal mitochondria can be achieved in old people's muscles through a program of "concentric" contractions.

Other GABAergic agents are able to functionally restore damaged mitochondria,

but in these studies, the quality of the DNA wasn't investigated. Piracetam intensifies oxygen consumption in damaged mitochondria, for example following injury or oxygen deprivation, especially in older animals. The restoration is permanent, so in this case the substance isn't acting just as a more easily metabolized source of energy, as was believed to be the mechanism in the case of the ketone body supplement.

Many people still believe that increasing oxygen consumption necessarily increases free radical activity and shortens the life-span, and that the life extension produced by caloric restriction results from reduced oxygen consumption. The fact that estrogen suppresses mitochondrial oxygen consumption is being used to justify using it to treat aging and dementia. But caloric restriction doesn't reduce oxygen consumption per gram of tissue, and sometimes increases it. Uncoupling mitochondria, so that they consume more energy without producing more ATP, appears to produce an extension of lifespan approximately equal to the increased rate of energy and oxygen consumption (data discussed in Speakman, 2003). Increasing the metabolic rate has effects similar to restricting calories. Supplementing thyroid, increasing saturated fats such as MCT and coconut oil, and restricting polyunsaturated fats, can increase the metabolic rate.

Piracetam (like other GABAergic agents) very effectively decreases lipid peroxidation (Novikov, et al., 1996), despite increasing metabolic activity. While decreasing oxidative damage and increasing ATP production, it also lowers the activity of the cells' important antioxidant enzymes (Keil, et al., 2006). When a cell isn't being damaged, those adaptive enzymes aren't required to be so active. (Many publications argue that certain products are "beneficial because they increase the antioxidant enzymes," but in fact almost any kind of injury will increase those protective enzymes.)

If mitochondria aren't damaged, for example in healthy young animals, piracetam doesn't greatly increase their activity. It simply restores them when they are damaged.

The mitochondria, besides producing energy and regulating calcium and other minerals, are the source of the GABAergic steroids. Since mitochondria contain "valium receptors" or GABA receptors, their high concentration in the region of synapses has probably sometimes been interpreted as showing "membrane receptors." But wherever they are, mitochondria are powerful agents of cellular interactions and regulation.

The carbon dioxide produced by mitochondria is involved in regulating ions and cellular electrical polarization, and protecting against free radicals. The energized and polarized cell retains magnesium and potassium, and excludes sodium and calcium. Increasing magnesium favors the protective inhibitory state, and is sometimes given intravenously to stop seizures. Adequate sodium in the diet is necessary for efficient retention of magnesium, and sodium is also required for the binding of glutamate. Lithium can replace sodium in activating glutamate removal (Menaker, et al., 2006), and it protects the brain against excitotoxicity (Chuang, 2004).

Breathing carbon dioxide has been used to stop seizures, and the drug, acetazolamide, which increases the body's retention of CO2, is sometimes used for epilepsy. Increased carbon dioxide protects the brain against a variety of factors (e.g., Simon, et al., 1993), and is probably involved in glutamate uptake.

Niacinamide, one of the B vitamins, happens to have GABAergic sedative activity, but it also has two other important effects. It can suppress lipolysis and lower circulating free fatty acids, reducing their interference with the use of glucose, and when the

mitochondria are already damaged, it can reduce the formation of lactic acid, by allowing the sugar to be fully oxidized. Forming the coenzyme NAD, niacin is responsible for maintaining an appropriate balance between oxidation and reduction (as the main cellular reductant), protecting cells from oxidative stress. (Shen, et al., 2003; Singh, et al., 2005; Kang, et al., 2006; Watanabe, et al., 2006; Kao, et al., 2007; Su, et al., 2007). The glutamate transporter must be kept in the reduced state to bind glutamate and stop the excitatory process (Trotti, et al., 1997).

Maintaining an adequate supply of glucose is directly protective against excitotoxicity (e.g., Flavin, et al., 1993), and helps to prevent stress reactions systemically.

Thyroid hormone (which has a reciprocal relation to estrogen) produces many relaxant effects, such as rapid relaxation after the Achilles tendon reflex contraction, reduced blood pressure, and deeper sleep, but its supportive effects on the GABA system are seldom considered in relation to therapies. It is essential for producing carbon dioxide, the neurosteroids, and ATP. Magnesium is retained in cells largely by its association with ATP, and it helps to keep the ATP level high. Thyroid is needed for preventing excessive estrogen stimulation, and for controlling adrenaline and serotonin. But it also directly interacts with the GABA system, supporting the protective inhibitory functions (Zamoner, et al., 2006; Gilbert, et al., 2007; Ortiz-Butron, et al., 2003).

Inhibitors of estrogen synthesis are being considered for use in controlling epilepsy (Reddy, 2007), but aspirin and progesterone and thyroid can produce similar results.

When mitochondria are functioning fully, either glucose or saturated fats can safely provide energy. Some glucose or saturated fat can be converted to polyunsaturated fats, that can be used as regulators or signals, for example to activate the formation of stem cells. But those PUFA don't create disruptive cascades of increasing excitation or inflammation or excessive growth, and, from the evidence of animals that are fed fat free diets, or diets lacking omega -3 and omega -6 fatty acids, they aren't toxic to mitochondria.

When a healthy cell is excited, the mitochondria become more active, and their energy needs may exceed the amount of glucose available, leading to the formation of ketone bodies. Glucose deprivation seems to be a fundamental signal of stress, and the formation of ketone bodies is possibly the most primitive defensive reaction to stress. They protect nerves from excitatory oxidative damage (Noh, et al., 2006), inhibit mitochondrial production of reactive oxygen species during excitation (Maalouf, et al., 2007) and inhibit tumor growth and lactate production (Magee, et al., 1979). Increased thyroid hormone can increase ketone formation (Riou, et al., 1980; Bartels and Sestoft, 1980).

The idea of synaptic membrane receptors often leads people to think of cellular inhibition in terms of raising a cell's threshold for producing an all-or-none membrane response to stimulation. But the inhibitory and excitatory systems interact at all levels of function and structure, reciprocally modifying each other.

In response to signals for excitation or inhibition, for example, the quantity of GABA and GABAergic steroids such as progesterone will change, in response to increases or decreases in the enzymes that produce or eliminate them, and changes in concentrations of precursor molecules. The quantity and sensitivity of the various types of "receptor" will change. Proteins that bind and inactivate GABA and other regulators will change in quantity and effectiveness. The rate at which energy is produced will change, along with the rates of cellular reconstruction and

decomposition. The cells' metabolic changes will produce signals that affect adjoining cells and the organism's physiological processes, including circulation, respiration, and readiness for stress.

In the "normal" course of aging, good tissues atrophy, and may be partly replaced by fibrotic tissues, and in that environment, tumors and disorganized structures of various kinds develop. The highs and lows, the daily cycles of mental and physical activity, tend to be leveled, as the ability to produce metabolic energy declines.

The polyunsaturated fats suppress energy production, and that suppression is aggravated by their excitatory or inflammatory effects, which lead to increased excitation by other intrinsic factors such as estrogen, cytokines, serotonin, and peptide hormones, that intensify the problem of maintaining energy production. Stimulation, without corresponding appropriate inhibition and adequate energy, skews the path of development, toward aging and sickness.

When each cell is fully energized and stabilized, it is sensitive and responsive to its surroundings, supporting the organism's adaptability.

Although caffeine is a stimulant that can offset the sedative effects of GABA, it also functions as a neuroprotectant, protecting against some of the effects of glutamate (Chinopoulos, et al., 2004). It is also a very good source of two other protective factors, magnesium and niacin. "French-roast" (dark) coffee is an especially rich source of niacin, which might be responsible for the "French paradox," the low incidence of heart disease in a country that doesn't follow the AHA's "heart protective diet."

March 2011 newsletter:

Serotonin: Effects in disease, aging and inflammation

Interpreting medical publications requires some skills that aren't needed for understanding more strictly scientific reports, because medical writing often takes into account the fact that physicians spend most of their time interacting with the public, rather than studying. The public's understanding of medicine is shaped by "public relations," by the introduction of words and concepts that frame the argument. (The linguist George Lakoff summarized the essence of public relations by observing that people reject facts that are outside their view of reality, their mental framework.) Television and public schools now frame the worldview of the affluent cultures, according to the needs of the ruling powers. Long before specific prescription drugs could be advertised directly to consumers, the medical and pharmaceutical industries were creating a favorable frame for their products.

Many years ago, public relations experts used expensive opinion polls to judge the effectiveness of their efforts, but now there is a convenient way to see how the general public is thinking**:** Wikipedia, the internet encyclopedia. The success of corporate advertising can be seen in their recent article on serotonin, which says "It is a well-known contributor to feelings of well-being; therefore it is also known as a 'happiness hormone' despite not being a hormone."

The culture that has happy and unhappy hormones was a culture in which each hormone had a receptor, a substance in a cell which, when its ligand was bound to it, made the cell do something. Although that culture still has influence in the 21st century, discoveries made between 1940 and 1970 showed that those mechanical ideas of receptors didn't reflect biological reality. Albert Szent-Gyorgi and the Pullmans showed that the electronic qualities of molecules determined their functions, and Szent-Gyorgyi showed that the state of the cell, tissue, and organism governed the effect of hormones and drugs. In the 1960s, substances with very different biological effects, such as acetylcholine and adrenaline, were shown to be selectively bound to the same cellular site in some cells. It was primarily the drug industry that created and sustained the specific receptor doctrine. That doctrine suited the recognition of their public relations-marketing experts, that successful advertising had to be directed at the sixth-grade educational level. The ideas of bioelectronics and context-sensitive molecules, like morphogenetic fields, were just too complicated to sell well.

Although metaphorical thinking can be creative and productive, metaphors mustn't be taken literally. The identification of multiple types of receptor for a given natural substance involves the use of different substances as metaphors or similes for the natural substance. That type of pharmacology is slowly being replaced by an attempt to understand state-dependent sensitivities. The energetic state of a cell, and of the whole organism, determines the meaning of events and conditions, such as the presence of the "regulatory substances."

The receptor culture can be tentatively disregarded when thinking about the history of serotonin. In the 1930s Vittorio Erspamer identified an amine in the intestine, that caused the intestine to contract. Then a group in England extracted an amine from serum that caused blood vessels to contract, and identified its chemical nature. Later, Erspamer showed that the intestinal amine and the vascular amine were chemically the same. The English group who had identified the substance by extracting tons of beef blood, wanted to find sensitive ways to assay it for further studies, and in 1951 they gave a sample to a pharmacologist, John Gaddum, who tested its effects on tissues including blood vessels and rat uteruses.

Gaddum tested the serotonin in combination with a variety of other drugs, including ergot derivatives, that he knew acted on smooth muscles, and very soon observed that LSD blocked the effects of serotonin. Since he knew that LSD produced mental effects (Sandoz had distributed samples of it to researchers in 1947), he reasoned that the brain might also contain serotonin, and by 1952 was able to

demonstrate that it does contain small amounts of it. A couple of years later he suggested "that the mental effects of lysergic acid diethylamide are due to interference with the normal action of this HT [5-hydroxytryptamine, serotonin]." At the Rockefeller Institute in New York, Woolley and Shaw also saw the antagonistic effects on smooth muscle, and drew similar conclusions about the brain. Erspamer (Renic. sc. farmital. **1**, 1, 1954) showed that LSD was a highly effective antagonist against the antidiuresis caused by serotonin (enteramine).

Around the same time, in the early 1950s, several people recognized that the symptoms produced by administering an excess of serotonin were similar to those experienced by people with intestinal tumors called argentaffinomas or carcinoid tumors, which are usually in the small intestine or appendix. The normal intestine contains about 95% of the serotonin in the body (and the brain normally contains only about 1%), and in the normal person only about 1% of the dietary tryptophan is converted to serotonin. But in an advanced case of carcinoid, 60% of the tryptophan can be turned into serotonin. Especially if the tumor has invaded the liver, the serotonin won't be destroyed by the liver in the usual way, and will circulate in the bloodstream at high levels, producing symptoms of flushing, sweating (sometimes dark-colored), diarrhea (serotonin stimulates small intestine smooth muscle, but inhibits the large [Bennett & Whitney, 1966]), nausea, anxiety, reduced urination, muscle and joint pains, and, in late stages, very often cardiovascular disease (especially inflammation, fibroma and calcification of the valves in the right side of the heart) and aggressive behavior (Russo, et al., 2004) and psychosis.

Testing Gaddum's idea of antagonism between LSD and serotonin in humans, Montanari and Tonini found that intramuscular injections of serotonin antagonized the psychological effects of LSD. Other drugs, especially other ergot derivatives, were more successful than LSD in blocking the effects of serotonin (Dubach and Gsell, 1962). There have been suggestions that pregnancy hormones could control serotonin excess (McCullough and Myers, 1965). Since estrogen promotes serotonin, progesterone is likely to be the protective factor (Donner & Handa, 2009; Hiroi, et al., 2006; Berman, et al., 2006; Bethea, et al., 2000).

More recently (Spigset, et al., 2004), it was found that LSD binding to a presumed serotonin receptor was low in carcinoid patients, supporting the idea of antagonism between the substances, but in the older studies symptoms, rather than competition for binding to certain proteins, were the focus of attention. The effects produced by injections and oral doses of synthetic serotonin, and of substances that block the synthesis of serotonin, were studied in both animals and humans. When a symptom such as clotting, flushing, or diarrhea is produced by serotonin itself, or prevented by a blocker of serotonin synthesis, "receptors" aren't an issue.

Aldous Huxley was one of the first people to think about the general biological meaning of drugs such as LSD. Referring to the ideas of Henri Bergson and William Blake, he suggested that the brain usually acts as a filter, or "reducing valve," to make us disregard most of the information we are receiving through our senses, and that the psychedelic drugs temporarily remove the filter, or open the sensory reducing valve. Bergson had suggested that the filter was a practical measure needed to allow us to focus on practical survival needs; Blake had suggested that the doors of perception were kept closed for cultural reasons.

Some recent reviews have discussed the evidence supporting the serotonin system as primarily inhibitory and protective (Anne Frederickson, 1998, Neil Goodman, 2002). Goodman describes the serotonergic system as one of our "diffuse neuroregulatory systems," and suggests that drugs such as LSD weaken its inhibitory, filtering effect. (Jacobs, 1983, 1987: by changes in the effects of serotonin in the brain, produced by things that affect its synthesis, release, catabolism, or receptor action.) LSD depresses the rate of firing of serotonergic nerves in the raphe nuclei (Trulson and Jacobs, 1979) causing arousal similar to stimulation of the reticular formation, as if by facilitating sensory input into the reticular formation (Bowman and Rand, 1980).

In European culture, some people--e.g., Plato, Descarte, Locke, Eccles, probably even B.F. Skinner--have believed that mind and body are essentially different things (analogous to computer hardware and its programs), while another tradition--Blake, Lamarck, Darwin, C.L. Morgan, Pavlov, Reich, C.R. Cloninger, for example--has emphasized the continuity of consciousness and character with the body.

Understanding the authoritarian personality has been an important issue in the 20th century. Wilhelm Reich used some old ideas about the nervous system that were current near the beginning of the century, and Cloninger (1995) and others (Netter, et al., 1996, Ruegg, et al., 1997, Gerra, 2000), toward the end of the century, were able to incorporate the newer information about the serotonergic-dopaminergic antagonisms. In this newer view, high serotonin production causes behavioral inhibition and harm avoidance, which are traits of the authoritarian personality, while antiauthorians tend to have "novelty seeking" personalities, with high dopamine and low serotonin functions.

In the 1960s, experimenters put electrodes into a chicken's optic nerve, and when the chicken saw a checkerboard pattern, they could measure a patterned electrical activity in the nerve. Without the light stimulating the retina, the nerve was quiet. But when they gave the chicken LSD or similar chemicals, they recorded patterned electrical activity in the nerve, in the absence of external stimulation. Around the same time, other experimenters showed that retinal fatigue quickly desensitized the retina, preventing the transmission of impulses to the brain, except when the light pattern corresponded to something familiar, showing that impulses from the brain are always involved in renewing, in patterned ways, the sensitivity of the retina.

The latter experiment shows that everyone's perception involves an outward-directed activity of the brain, and the experiments using the chemical stimulants suggested that the intensity of the outward-directed action can vary.

The inhibitory serotonergic "harm avoidance" system, and the opposing excitatory activating "novelty seeking" systems are constantly being influenced by many factors, including nutrition, hormones, environmental challenges and opportunities, social interactions, seasons, and the rhythm of night and day alternation.

Several kinds of research are now showing that the effects of the environment on the serotonergic system and its antagonists can influence every aspect of health, not just the personality.

For example, there have been suggestions that early life isolation of an animal can affect its serotonergic activity and increase its anxiety, aggression, or susceptibility to stress (Malick and Barnett, 1976, Malick, 1979, dos Santos, et al, 2010), and these effects are associated with increased risk of becoming depressed, and developing organic problems. Animals kept in darkness (or with blurring lenses) become nearsighted, as the eyeball grows longer under the influence of increased serotonin, and the eyes are protected against myopia by serotonin antagonists (George, et al., 2005). The incidence of myopia is increasing, at least in countries with industrialized economies, and is more common in females.

Migraine headaches are also increasing in incidence. By the end of the 1950s, it was widely accepted that migraine headaches and associated symptoms including nausea and visual disturbances were caused by an excess of serotonin, and antiserotonin drugs of various types were being used for treatment. In one of the early studies of the use of LSD in psychotherapy, some of the patients noticed that their chronic headaches had stopped. Cluster headaches have also responded well to LSD and similar drugs (Sewell, et al., 2006).

Women have migraines more often than men do, and they tend to occur in association with ovulation or menstruation. Estrogen inhibits monoamino oxidase, MAO, especially the A form that is most active in detoxifying serotonin, and it increases the enzymes that control the rate of serotonin synthesis. During serotonin excess, the veins and capillaries of the pia mater are engorged with blood, while circulation to

the brain generally is depressed. Visual symptoms are probably produced by contriction of arterioles, while the pain is associated with engorged veins. Progesterone activates the MAO-A, and has other antiserotonin effects on blood vessels and nerves.

Recently (Shansky, et al., 2010; Figueiredo, et al., 2007), females have been found to be more susceptible to stress, and to have reduced uptake of serotonin (prolonging its effects), which increases glucocorticoids and ACTH. Kendler, et al. (2005) have found that people with reduced serotonin uptake are more susceptible to stress-induced depression.

The increase of inhibitory serotonin with stress and depression is probably biologically related to the role of serotonin in hibernation, which is an extreme example of "harm avoidance" by withdrawal. A diet high in polyunsaturated fat increases the tendency to go into hibernation, probably by increasing the brain's uptake of tryptophan. When this is combined with an increasingly cold environment, the form of MAO that removes serotonin decreases its activity, while the form that removes norepinephrine increases its activity. The metabolite of serotonin, 5-HIAA, decreases, as the effect of serotonin increases.

In experiments to investigate the mechanism of hibernation, animals were injected with serotonin, at different environmental temperatures. In a cool environment, the serotonin caused their temperature to fall, by decreasing their heat production, and increasing their loss of heat (by causing vasodilation in the skin, "flushing"). In a hot environment, serotonin can cause the animal's temperature to rise.

Serotonin can reduce the production of energy by inhibiting mitochondrial respiratory enzymes (Medvedev, 1990, 1991), and by reduction of oxygen delivery to tissues by vasoconstriction. It also appears to interfere with the use of glucose (de Leiva, et al., 1978, Moore, et al., 2004).

The brains of people with Alzheimer's disease have a decreased ability to metabolize glucose, and high cortisol contributes to the altered glucose metabolism, and to the destruction of nerve cells. People with Cloninger's "harm avoidance" personality trait, which is closely associated with serotonin (Hansenne, et al., 1999), are more likely to develop dementia (Clément, et al., 2010). These observations are consistent with the stress-susceptibility of people with high serotonin exposure, and to the effects of cortisol on nerves and glucose-derived energy production.

Researchers in Brasil have suggested that the serotonergic system facilitates conditioned fear, while inhibiting the fight or flight reaction, and that this can protectively limit the stress response (Graeff, et al., 1996). "5HT systems reduce the impact of impending or actual aversive events. Anticipation of an aversive event is associated with anxiety and this motivates avoidance behaviour" (Deakin, 1990). In a stressful situation, the serotonergic nerves can prevent ulcers. In other contexts, though, increased serotonin can cause ulcers.

The protective, defensive reactions involving serotonin's blocking of certain types of reaction to ordinary stresses, are similar to the effects of serotonin in hibernation and in Alzheimer's disease (Mamelak, 1997; Heininger, 2000; Perry, et al., 2002). In those extreme conditions, serotonin reduces energy expenditure, eliminating all brain functions except those needed for simple survival. These parallels suggest that improving energy production, for example by providing ketones as an alternative energy source, while reducing the stress hormones, might be able to replace the defensive reactions with restorative adaptive nerve processes, preventing or reversing Alzheimer's disease.

One of the factors promoting excess cortisol production is intestinal irritation, causing absorption of endotoxin and serotonin. Fermentable fibers (including pectins and fructooligosaccharides) support the formation of bacterial toxins, and can cause animals to become anxious and aggressive. Fed to horses, some types of fiber increase the amount of serotonin circulating in the blood. Grains, beans, and other seeds contain fermentable fibers that can promote intestinal irritation.

The liver has several ways to detoxify endotoxin and serotonin, but these can fail as a result of poor nutrition and hypothyroidism.

The lung can bind and destroy any excess serotonin that reaches it. A lack of carbon dioxide makes platelets release their stored serotonin, and it probably has the same effect in the lung endothelial cells. Without being able to bind the serotonin, the enzyme (indoleamine 2,3-dioxy- genase) would be unable to destroy it.

An excess of tryptophan in the diet, especially with deficiencies of other nutrients, can combine with inflammation to increase serotonin. Polyunsaturated fatty acids promote the absorption of tryptophan by the brain, and its conversion to serotonin. (A "deficiency" of polyunsaturated fat decreases the expression of the enzyme that synthesizes serotonin [McNamara, et al., 2009).

Some fruits, including bananas, pineapples, and tomatoes, contain enough serotonin to produce physiological effects in susceptible people.

Besides avoiding foods containing fermentable fibers and starches that resist quick digestion, eating fibrous foods that contain antibacterial chemicals, such as bamboo shoots or raw carrots, helps to reduce endotoxin and serotonin. Activated charcoal can absorb many toxins, including bacterial endotoxin, so it is likely to reduce serotonin absorption from the intestine. Since it can also bind or destroy vitamins, it should be used only intermittently. Frolkis, et al. (1989, 1984) found that it extended median and average lifespan of rats, beginning in old age (28 months) by 43% and 34%, respectively, when given in large quantities (equivalent to about a cup per day for humans) for ten days of each month.

The amino acid theanine, found in tea, has been reported to decrease the amount of serotonin in the brain, probably by decreasing its synthesis and increasing its degradation. This seems to be the opposite of the processes in hibernation. Progesterone, thyroid, and niacinamide (not nicotinic acid or inositol hexanicotinate) are other safe substances that help to reduce serotonin formation, and/or accelerate its elimination. (Niacinamide seems to increase serotonin uptake.)

To provide usable energy to the over-stressed brain (and heart), R.L. Veech has advocated the use of ketones, but the pure chemicals are expensive to make. An easily available and inexpensive source of ketones (in the form of ketoacids, which can be converted to amino acids if they aren't needed for energy) is the juice extracted(with a centrifugal juicer) from raw potatoes, which also contains proteins and other nutrients. The juice can be scrambled like eggs, and is usually tolerated even by very debilitated people.

Hypothyroidism is a very common cause of increased serotonin (e.g., Henley, et al., 1998), and if the thyroid hormone is supplemented until symptoms are resolved, it's likely that the serotonin will have been normalized.

Endotoxin, stress, depression:
Serotonin, starches, fatty acids, and antidotes

Increasingly, intestinal serotonin is being recognized as a factor in osteoporosis, migraine, irritable bowel syndrome, appendicitis, and cancer. From ancient times until about 100 years ago, the bowel had a very important place in medical practice, with purgatives and enemas being recommended for headaches, persistent coughs, seizures, and many chronic diseases. Pavlov studied the digestive system as a way to understand the mind, because it's where we interact most closely with the environment.

Up to Pavlov's time, traditional medicine thought in terms of achieving balance in the organism, using metaphors such as the four humors (phlegm, blood, yellow bile and black bile) and the four personality types---phlegmatic, sanguine, choleric, and melancholic.

In western Europe and the US during the 19th century, divisions in medical doctrine began to appear between traditional, "empirical" practitioners and advocates of a new "rational," reductionist allopathic doctrine who were coming to believe that disease had its origin in cells and their defects of form or function. These "scientific physicians" began a major propaganda campaign to ridicule blood-letting and purging as examples of the unscientific practices of their competitors. The idea of internal toxins itself was ridiculed. A gastroenterology professor (Walter C. Alvarez) used his newspaper column to argue against the old ideas, for example that toxins absorbed from the intestine caused headaches. He described putting wads of cotton into the rectums of his medical students, and a considerable number of them developed headaches while the cotton was in place. That, he asserted, disproved the idea that absorbed toxins were the cause of headaches. It didn't really disprove anything, but it contributed to the culture that was discouraging the use of laxatives. Russian researchers, who were still working in Pavlov's holistic tradition, found that inflating a balloon in an animal's intestine didn't have any observable effect in a normal animal, but when the animal's blood sugar was lowered, the stretching of the intestine would produce a wide range of symptoms, from asthma to seizures. It is likely that some of Alvarez's students had low blood glucose, and were more susceptible than others to the abnormal stretching of the rectum.

Inflammation of the bowel used to be recorded frequently as the cause of death of older people, but now it's seldom mentioned in autopsy reports as the cause of death, if it's mentioned at all.

Hans Selye had noticed that intestinal bleeding was a standard feature of being sick, and it became a defining feature of his concept of stress. Old people sometimes get ulcers in their colon or rectum, adjacent to lumps of hardened fecal material. Selye devised animal experiments, in which he showed that an interference with blood circulation that normally didn't produce serious harm, would cause similar (stercoral) ulcers, and also paralysis of the hind legs, if he injected serotonin into the animal. If the anti-serotonin drug, cyproheptadine, was given to the animal before the serotonin, they were protected. The ulcers required the combination of restricted blood circulation, excess serotonin, and the presence of feces in the lower intestine. Without the serotonin, the other two factors failed to produce the ulcers (1966). In a previous experiment, he had demonstrated that the combination of impaired circulation with serotonin would cause severe muscular dystrophy (1965).

Selye's research group showed how closely the digestive system and the nervous system interact, but they didn't go very far in exploring the effects of diet on the nervous system.

Just friction, or scratching or stretching the intestine is enough to cause it to release serotonin into the bloodstream. Serotonin increases the permeability of the intestine and blood vessels, and so is likely to be a major cause of the absorption of endotoxin (and other harmful material) during intestinal irritation or stress. The biological meaning of serotonin might be very different without endotoxin, but that hasn't been investigated.

Bacterial endotoxin increases serotonin release from the intestine, and increases its synthesis in the brain (Nolan, et al., 2000) and liver (Endo, 1983). It also stimulates its release from platelets, and reduces the lungs' ability to destroy it. The formation of serotonin in the intestine is also stimulated by the lactate, propionate and butyrate that are formed by bacteria fermenting fiber and starch, but these bacteria also produce endotoxin. The inflammation-producing effects of lactate, serotonin, and endotoxin are overlapping, additive, and sometimes synergistic, along with histamine, nitric oxide, bradykinin, and the cytokines.

There have been some studies showing that bacterial fermentation in the intestine can cause many symptoms, including behavioral changes.

For example, a diet of soy protein increases aggression in monkeys (Simon, et al., 2004) and chickens (McKeegan, et al., 2001).

When various fermentable carbohydrates were fed to rats, they became anxious and agressive, and these changes in behavior corresponded to the fermentation of these materials by bacteria in the lower intestine, with the production of lactic acid (Hanstock, et al., 2003, 2004).

Dietary fiber has been promoted for a long time, and for many reasons---John Harvey Kellogg argued that it prevented dirty thoughts, the cholesterol people argued that it would lower cholesterol, Denis Burkitt, in the 1970s, suggested that it could prevent colon cancer. When Burkitt visited the US and saw that oat bran was being recommended, he commented that the main fiber in the African diet he had studied was potato. By the 1980s, studies in animals were showing that some kinds of fiber, including **oat bran, pectin, corn bran, metamucil, undegraded carrageenan, agar, psyllium, guar gum, and alfalfa,** were carcinogenic, increasing the incidence of colon cancer, and possibly ovarian and breast cancer (Toth, 1984, Jacobs, 1986, Goodman, et al., 2002).

Many advocates of increasing dietary fiber argue that butyric acid is a protective factor produced by bacterial decomposition of starch and fiber, and it does (at least in vitro) sometimes cause cancer cells to differentiate into normal cells. However, it accelerates the growth of intestinal cells, and when that is combined with toxins it might act as a tumor promoter. The lactic acid produced by bacteria and by the inflamed intestine itself is now recognized as an important factor in the development of cancer.

The upper part of the small intestine is sterile in healthy people. In the last 40 years, there has been increasing interest in the "contaminated small-bowel syndrome," or the "small intestine bacterial overgrowth syndrome." When peristalsis is reduced, for example by hypothyroidism, along with reduced secretion of digestive fluids, bacteria are able to thrive in the upper part of the intestine. Sugars are very quickly absorbed in the upper intestine, so starches and fibers normally provide most of the nourishment for bowel bacteria.

Besides avoiding gums and other "soluble fiber," and starches that aren't quickly digested, there are several things that can protect against the toxic effects of bacterial degradation products. Beans are famous for their gas-producing polysaccharides, but all grains and vegetables and firm under-ripe fruits contain starches that resist our digestive enzymes, but that can provide food for bacteria. Undercooked starch, and starches combined with enzyme inhibitors (including polyunsaturated fats), tend to be fermented by bacteria. New technology in the orange juice industry has converted normal pulp to soluble fiber that supports bacterial fermentation.

A high ratio of calcium to phosphorus reduces the breakdown of fibers, and this probably contributes to some of the protective effects of a

large amount of calcium in the diet, for example reduction in the incidence of bowel and ovarian cancer.

A few plant fibers have a high proportion of cellulose, that resists bacterial attack, combined with antibiotics that suppress bacterial growth, but in most grains and vegetables, and many fruits, cellulose is combined with fibers that support bacterial growth. Fats, especially saturated fatty acids, have antiseptic properties, and when they are combined with starches and fibers they help to suppress bacterial growth. Their effects can be seen in various ways, including protection against the anxiety caused by fermentation (Prasad and Prasad, 1996).

Thyroid hormone increases digestive activity, including stomach acid and peristalsis, and both thyroid and progesterone increase the ability of the intestine to absorb sugars quickly; their deficiency can permit bacteria to live on sugars as well as starches.

Pavlov's and Anokhin's understanding of the organism in terms of its integration of perceptions of the actual situation, including its needs, and its projection of the possibility of satisfying those needs, gives us a way to understand some of the ways that our digestive system interacts with our physical health and our moods and emotions. Anokhin, in analyzing Pavlov's Reflex of Purpose and Exploratory Reflex, described the way that the cortex of the brain creates a model of the world, including information about the present state of the organism. Anokhin called this model of the situation the Acceptor of Action, because it was the framework for evaluating behavior. A properly functioning organism is always projecting or imagining future possible situations, and projecting or imagining its actions in those situations, evaluating the possibilities.

Any particular external situation can create stress or not, depending on what it means to the individual. The perception of a possibly good outcome mobilizes the creative adaptive abilities, in a functional system that includes an external goal and relevant physiological processes; the failure to see possibility in the situation--anticipating failure rather than success--demobilizes the systems of adaptation, and the excitation caused by unsatisfied needs produces generalized catabolic processes.

As the organism prepares to enact these imagined possible futures, it mobilizes the appropriate resources, activating some systems and inactivating other systems, constructing, consuming and redistributing its own substance, while assimilating substances from the environment. The anabolic hormones, such as thyroid, and the tissue-catabolic hormones such as cortisol, act both locally and systemically, according to various regulatory processes, mainly nervous processes. A functional system is created for achieving the goal. As the organism achieves its purposes or adapts, the catabolic hormones will subside.

Sensory nerves in the intestine contribute to the organism's assessment of the situation--the Acceptor of Action--and motor nerves adjust the state of the intestine and other organs. The interplay between the state of the intestine and the assessed state of the stressful situation determines whether the individual will withdraw (often with incontinence of the bowel and bladder) or persist and struggle to adapt.

Defensive aggression is probably a response intermediate between fearful giving up and confident achievement. When a rat is restrained, held down on its back, it quickly develops ulcers, but if it has a stick to bite, it is very resistant to the formation of the ulcers. The ability to do something with a defensive meaning prevents the excessive production of serotonin and its consequences, such as increased production of cortisol and other stress hormones, and disturbance of cirulation and energy production. Endotoxin and prostaglandins activate these same systems, and progesterone and aspirin are among the protective factors that can oppose those effects.

When physical and mental activity are intensified to meet an adaptive crisis, the adrenergic sympathetic nervous system optimizes muscular energy production, but inhibits the digestive system. In the state of anxious-helpless withdrawal, the parasympathetic and serotonergic systems demobilize the active neuro-skeletomuscular systems, and activate the bladder, intestine and stomach, tending to empty the

contents by causing diarrhea, vomiting, and urination. Serotonin reduces energy production in muscles; this is probably related to the muscular dystrophy it produced in Selye's experiments, and the myopathy produced by tryptophan (Castot, et al., 1991). Antiserotonin drugs are used for controlling diarrhea and vomiting, and some of them are protective against ulcers (Ramesh, et al., 2009).

Chronically elevated cortisol is commonly seen in depressed people, but giving a supplement of cortisol is effective in relieving depression. Both cortisol and the pituitary corticotropic hormone that stimulates its production, ACTH, have some antidepressant effects, and they inhibit the hypothalamic corticotropin release hormone, CRH. CRH is more directly associated with depression than cortisol is, and it by itself activates many inflammatory processes, including the release of histamine, cytokines, and nitric oxide. CRH is promoted in the hypothalamus (and in many other tissues) by inflammation, endotoxin, serotonin, interleukins, and prostaglandins, but also by the perception of unavoidable difficulties.

Besides cortisol, progesterone and androgens are internal factors that decrease the activity of CRH. Estrogen and hypothyroidism increase its activity.

The convergence, interaction, and summation of inflammatory molecules with the perceived meaning of a situation is a subject carefully avoided by those who think of the organism as a sum of its molecules and cells. They accept that transmitter molecules and receptor molecules regulate behavior, and influence perception, but they can't explain how understanding and interpretation can make the profound differences in feeling, behavior, and biochemistry that they in fact do make.

The model of nerves as on-off switches, governed by the state of their membrane, has made the problem of integrating meaning with chemistry seem impossibly complex. In recent years it has been recognized that nerves can produce or respond to more than one kind of signal, but few people have understood nerve cells in a way that could allow individual cells to handle complex and subtle signals, and to make rational judgments based on such signals. P.K. Anokhin, G. Albrecht-Buehler and a few others have observed the importance of recognizing cellular complexity, and the ability of cells to integrate complex information. The cell physiology of Gilbert Ling and Albert Szent-Gyorgyi demonstrated the basis on which these complex integrating processes can be understood.

Nerves and muscle cells should be considered together, because they respond to many things in similar ways. The membrane people don't like to think that nerves have any contractile properties, but in fact they do twitch slightly when stimulated, showing that it is the entire cytoplasm that responds to information, not the hypothetical plasma membrane. When they are overstimulated, they swell, as muscles do when they are fatigued. When a muscle is stretched while it's trying to contract (as in running downhill; this is called "eccentric contraction") it becomes inflamed, and the structural damage can be cumulative. By exercising muscles with "concentric contractions," allowing them to shorten against resistance, the cellular damage can be repaired.

Stretching a nerve causes some metabolic changes similar to the muscle in eccentric contraction, but nerves are normally protected against injuries of that sort. However, very intense stimulation of a nerve fiber can disrupt its internal structure, causing "beading," an intermittent clumping of the nerve filaments and microtubules along the axon, as if the internal structure is contracting in segments, while the overall axon doesn't contract. With intense stress, the beaded fiber can separate into individual pieces, like droplets of cytoplasm, instead of the elongated cylinder. Long before stress causes it to disintegrate in that manner, it is likely that it causes it to lose its functional coherence.

The excessive stimulation of a cell increases its internal alkalinity, causing it to take up more water. The mediators of inflammation, such as CRH, serotonin, and endotoxin cause cell swelling and increased alkalinity. CRH and endotoxin can increase the susceptibility to seizures, but they can also block the ability of cells to respond to normal stimulation.

Serotonin, as an alkaloid, is bound and inactivated by acidic cells. Carbon dioxide, produced by respiration, normally keeps cells slightly acidic. Hyperventilation, or the production of less carbon dioxide and more lactic acid, causes serotonin to be released from platelets and other cells where it has been inactive, allowing it to enter other cells where it has its characteristic effects, increasing lactate, decreasing ATP (Assouline-Cohen, et al. 1998, Koren-Schwartzer, et al., 1994), increasing pH, and stimulating contraction or mitosis.

One of the very neglected mechanisms of serotonin's action is its ability to activate carbonic anhydrase, a class of enzymes that convert carbon dioxide to bicarbonate, and tend to increase the alkalinity of cells. Inhibitors of carbonic anhydrase are currently being investigate for their ability to stop the growth of cancer cells and to permit their recovery of normal functions. One of the carbonic anhydrase inhibitors, acetazolamide, has been used for many years to treat epilepsy, glaucoma, migraine, sleep apnea, mountain sickness--and even psychosis (Inoue, et al., 1984).

Serotonin's effects appear to be the result of its action on the microtubules or other elements of the cell skeleton (Bianchi, et al., 2003, Grass, et al., 2004), which are the main integrating elements of the cell. Chronic disturbance of the microtubules and neurofilaments, with inflammation and impaired energy production, is characteristic of Alzheimer's disease.

If the internal and external causes of stress converge, additively, on the cell's internal communication and integration system, then the basic resistance of the organism to stress can be increased by any of the factors which oppose the signals of stress.

Carbon dioxide, progesterone, and thyroid act on many of the factors that interfere with our ability to handle stress constructively. A diet that reduces fermentation and endotoxin, with an abundance of calcium--fruit, milk, and cheese, for example--can help to shift the balance away from lactic acid, estrogen, and serotonin, toward carbon dioxide, progesterone, and thyroid.

Gen Pharmacol. 1994 Oct;25(6):1257-62. **Serotonin-induced decrease in brain ATP, stimulation of brain anaerobic glycolysis and elevation of plasma hemoglobin; the protective action of calmodulin antagonists.** Koren-Schwartzer N, Chen-Zion M, Ben-Porat H, Beitner R. 1. Injection of serotonin (5-hydroxytryptamine) to rats, induced a dramatic fall in brain ATP level, accompanied by an increase in P(i). Concomitant to these changes, the activity of cytosolic phosphofructokinase, the rate-limiting enzyme of glycolysis, was significantly enhanced. Stimulation of anaerobic glycolysis was also reflected by a marked increase in lactate content in brain. 2. Brain glucose 1,6-bisphosphate level was decreased, whereas fructose 2,6-bisphosphate was unaffected by serotonin. 3. All these serotonin-induced changes in brain, which are characteristic for cerebral ischemia, were prevented by treatment with the calmodulin (CaM) antagonists, trifluoperazine or thioridazine. 4. Injection of serotonin also induced a marked elevation of plasma hemoglobin, reflecting lysed erythrocytes, which was also prevented by treatment with the CaM antagonists. 5. The present results suggest that CaM antagonists may be effective drugs in treatment of many pathological conditions and diseases in which plasma serotonin levels are known to increase.

Rosacea, Inflammation, and Aging: The Inefficiency of Stress

> ***Rosacea, or acne rosacea, has been defined as "vascular and follicular dilation involving the nose and contiguous portions of the cheeks . . ." that may involve persistent erythema with hyperplasia of sebaceous glands.***
>
> ***Stedman's Medical Dictionary 23rd edition.***

Light-skinned people, especially women between the ages of 30 and 50, sometimes develop a persistent redness of their cheeks and nose. It may begin as a tendency to flush excessively, but the blood vessels can become chronically dilated. Similar processes occur in dark-skinned people less frequently.

The eyes are sometimes involved, with redness of the exposed areas (conjuctival hyperemia). New blood vessels develop in the area, and the flow of blood through the affected tissue is greatly increased. The tissues become thickened and fibrotic, with the multiplication of fibroblasts and the increased deposition of collagen.

The cornea normally receives its oxygen from the air, and its nutrients from the aqueous humor. As rosacea of the eye develops, the blood vessels surrounding the cornea become increasingly visible, and, especially on the inner (nasal) side of the eye, the vessels tend to enlarge and become tortuous. Rhinophyma, or potato nose, has been described as a late development of rosacea.

Too often, the medical reaction is to give the condition a name, and to distinguish its variants as if they were different problems, and then to use the most direct means to eliminate the problem they have defined.

A typical attitude is that "Rosacea is an enigmatic disease with multiple exacerbations and remissions, and, unfortunately, treatment is directed toward symptomatic control rather than cure" (Randleman).

Lasers or other radiation, caustic chemical abrasion, surgical planing and dermal shaves, and other forms of surgery may be used to destroy the superficial blood vessels, and to reduce the enlarged nose or other irregularities. A few decades ago, when rosacea was believed to be the result of a local infection, antibiotics were used to treat it, and some of them, including tetracycline, helped. It was discovered that some antibiotics have anti-inflammatory actions, apart from their germicidal effects, and now it is very common to prescribe the chronic use of tetracycline to suppress symptoms.

Rosacea, and the fibrotic changes associated with it (pingueculae and pterygia in the eyes, rhinophyma of the nose, etc.), are much more than "cosmetic" issues, involving the skin and eye surface. If the invasive proliferation of blood vessels can be prevented, it's important to do that, because, for example, pannus/neovascularization of the cornea can seriously impair vision.

But possibly the strangest thing about the relationship of the medical profession to rosacea is that its essential features, invasive neovascularization and fibrotic growth, are of great interest when they occur elsewhere, and many physiological processes are known to regulate the growth of blood vessels and fibroblasts, but nearly all the attention given to rosacea and rhinophyma concerns control of symptoms for cosmetic effect. Rosacea is a physiological problem that deserves consideration in the light of all that's known about physiology and developmental biology.

The increased incidence of rosacea after the age of 30, and the fact that it occurs most commonly in the areas that are most exposed to sunlight (bald men sometimes develop it on the

top of the head), indicate that aging and irritation are essential causes. Stress, irritation (such as produced by ultraviolet or ionizing radiation or free radicals), and aging are known to cause disorganized growth of fibrous and vascular tissues in various parts of the body. The occurrence of these processes at the surface, where the changes can be observed immediately, and without invasive procedures, should have aroused wide interest among those who study kidney disease, diabetes, and other degenerative diseases in which fibrosis and neovascularization play important roles.

A localized stress or irritation at first produces vasodilation that increases the delivery of blood to the tissues, allowing them to compensate for the stress by producing more energy. Some of the agents that produce vasodilation also reduce oxygen consumption (nitric oxide, for example), helping to restore a normal oxygen tension to the tissue. Hypoxia itself (produced by factors other than irritation) can induce vasodilation, and if prolonged sufficiently, tends to produce neovascularization and fibrosis.

Sensitivity to the harmful effects of light can be increased by some drugs and by excess porphyrins produced in the body (and by the porphyrin precursor, delta-amino levulinic acid), leading to rosacea, so those factors should be considered, but too often alcohol (which can cause porphyrin to increase) is blamed for rosacea and rhinophyma, without justification. There are many ways in which poor health can increase light sensitivity. Some types of excitation produced by metabolites (or by the failure of inhibitory metabolites) can produce vasodilation, involving the release of nitric oxide (Cardenas, et al., 2000), setting off a series of potentially pathological reactions, including fibrosis. The nitric oxide increases glycolysis while lowering energy production. The excitatory metabolite glutamate, and nitric oxide, are both inhibited by aspirin (Moro, et al., 2000).

When blood flow in skin affected by rosacea was measured, circulation was 3 or 4 times higher than normal (Sibenge & Gawkrodger, 1992), and oxygen tension may be increased. An inability to extract oxygen from the blood, or to use it to produce energy, will produce the same hyperemia that would be produced by a lack of oxygen. These measurements suggest that mitochondrial defects would be the best place to look for a general cause of rosacea.

When mitochondria are damaged, active cells produce increased amounts of lactic acid, even in the presence of adequate oxygen. Otto Warburg identified this kind of metabolism, aerobic glycolysis, as an essential feature of cancer, and showed that it could be produced by stress, ionizing radiation, carcinogenic toxins, and even by a simple oxygen deficiency. Other investigators around the same time showed that lactic acid produces vasodilation (for example, in the cornea), and more recently it has been shown to promote the development of fibrosis, and it has been called a "phlogogen," a promoter of inflammation.

Riboflavin, vitamin B2, is an essential component of the mitochondrial respiratory enzymes, and it is very easily destroyed by light (blue light and especially ultraviolet). When it is excited by high energy light, it can spread the damage to other components of the mitochondria, including the cytochromes and the polyunsaturated fatty acids. The other B vitamins are affected when riboflavin's actions are disturbed.

Vitamin K is also extremely light sensitive, and it interacts closely with coenzyme Q in regulating mitochondrial metabolism. For example, mitochondrial Complex-I, NADH-ubiquinone reductase, is probably the most easily damaged part of the mitochondrion, and it is protected by vitamin K. Vitamin E, coenzyme Q, and the polyunsaturated fatty acids are also light sensitive, and they are more susceptible to free radical damage when vitamin K is deficient.

Niacinamide, one of the B vitamins, provides energy to this mitochondrial system. Under stress and strong excitation, cells waste niacinamide-NADH, but niacinamide itself has a sedative antiexcitatory effect, and some of its actions resemble a hormone. Estrogen tends to interfere with the formation of niacin from tryptophan. Tryptophan, rather than forming the sedative niacin (pyridine carboxylic acid), can be directed toward formation of the excitatory quinolinic acid (pyridine dicarboxylic acid) by polyunsaturated fatty acids. Excitation must be in balance with a cell's energetic resources, and niacinamide can play multiple protective roles, decreasing

excitation, increasing energy production, and stabilizing repair systems. The state of excitation and type of energy metabolism are crucial factors in governing cell functions and survival.

The polyunsaturated fatty acids, besides their interactions with estrogen and tryptophan metabolism, promote excitation and decrease energy production in several other ways. For example, they increase the excitatory effects of the glutamate pathways (Yu, et al., 1986; Nishikawa, 1994), and their breakdown products inhibit mitochondrial respiration (Humphries, et al., 1998; Picklo, et al., 1999; Lovell, et al., 2000).

The excess excitation that produces nitric oxide and lactic acid lowers the energy production of vascular cells, possibly enough to lower their contractile ability (Geng, et al., 1992), causing vasodilation. When flushing is caused by a mismatch between energy supply and energy demand, caffeine can decrease the vasodilation (Eikvar & Kirkebøen, 1998), but when vasodilation is caused more physiologically by carbon dioxide, caffeine doesn't have that effect (Meno, et al., 2005). In a study in which drinking hot water or coffee was compared with drinking room-temperature coffee or caffeine, it was found that the hot liquids caused flushing, but cool coffee and caffeine didn't.

Caffeine increases cells' energy efficiency, and by opposing the effects of adenosine (secreted by cells that are stressed and energy-depleted), it can inhibit vasodilation, angioneogenesis (Merighi, et al., 2007; Ryzhov, et al., 2007), and fibrosis (Chan, et al., 2006).

One nearly ubiquitous source of inappropriate excitation and energy depletion is the endotoxin, bacterial lipopolysaccharides absorbed from the intestine (Wang and White, 1999). That this ubiquitous toxin has a role in rosacea is suggested by the observation that intestinal stimulation, to speed transit through the bowel, immediately relieved symptoms (Kendall, 2002). Increased cortisol (Simon, et al., 1998) and sepsis (Levy, 2007) interfere with mitochondrial energy production.

Simple nervous blushing or flushing is usually considered harmless, and when a person is overheated, the reddening of the skin has the function of facilitating heat loss, to restore a normal temperature. But even nerve-regulated flushing can involve a distinct interference with mitochondrial respiration, and can stimulate the overgrowth of blood vessels.

Cancer's respiratory defect that Warburg identified, fermentation with lactic acid production even in the presence of adequate oxygen, was the result of some kind of injury to the mitochondria. He showed that one of the injuries that could produce aerobic glycolysis was a deficiency of riboflavin. He observed that tumors generally were anoxic, and that cancers typically appeared in the midst of tissue that was atrophying, and suggested that the cancer cells' survival was favored by their ability to live without oxygen. This may be relevant to the observations of many surgeons of a small cancer embedded in the fibrous tissue of large rhinophymas that have been removed.

The relatively high incidence of rosacea among women (some studies indicate that it may be 3 times as common in women as in men) isn't likely to be the result of greater sun exposure, so it's reasonable to look for hormonal causes.

In old age, it's well recognized that men's estrogen level rises. But the estrogen industry has convinced women that their estrogen declines as they get older. It's common knowledge that aging rodents often go into "persistent estrus," and that their estrogen levels generally increase with age (Parkening, et al., 1978; Anisimov and Okulov, 1981). Several studies in women have shown that serum estrogen levels rise from the teens into the 40s (Musey, et al., 1987; Wilshire, et al., 1995; Santoro, et al., 1996).

Other studies show that serum and tissue estrogen concentrations are not concordant, and that some tissues may contain several times as much estrogen as the serum (Jefcoate, et al., 2001). Local irritation increases tissue estrogen content.

The antiestrogens, especially progesterone, begin declining in the 30s, so that the rising estrogen has more effect on the tissues during those years. These are the years in which the incidence of rosacea rises suddenly. Rosacea develops later on average in men, whose estrogen levels rise significantly at later ages.

Estrogen's most immediate effect on cells is to alter their oxidative metabolism. It promotes the formation of lactic acid. In the long run, it increases the nutritional requirements for the B vitamins, as well as for other vitamins. It also increases the formation of aminolevulinic acid, a precursor of porphyrin, and increases the risk of excess porphyrin increasing light sensitivity. Both aminolevulinic acid and excess porphyrins are toxic to mitochondria, apart from their photosensitizing actions. Nitric oxide, glutamate, and cortisol all tend to be increased by estrogen.

Veins and capillaries are highly sensitive to estrogen, and women are more likely than men to have varicose veins, spider veins, leaky capillaries, and other vascular problems besides rosacea. Estrogen can promote angioneogenesis by a variety of mechanisms, including nitric oxide (Johnson, et al., 2006). "Estrogens potentiate corticosteroid effects on the skin such as striae, telangiectasiae, and rosacea dermatitis" (Zaun, 1981). Early forms of oral contraceptives, high in estrogen, were found to increase acne rosacea more than three-fold (Prenen & Ledoux-Corbusier, 1971).

Lactic acid, produced under the influence of estrogen, nitric oxide, or other problems of energy formation, besides causing vasodilation, also stimulates the growth of fibroblasts. Oxygen deprivation, or damage to mitochondria, will increase lactic acid formation, and so it will immediately cause vasodilation, and if the problem is prolonged, new blood vessels will grow, and fibrous connective tissue will increase. Estrogen stimulates collagen synthesis, and it has been associated with a variety of inflammatory and fibrotic conditions (for example, Cutolo, et al., 2003. Payne, et al., 2006, suggest the use of the anti-estrogen, tamoxifen, to treat rhinophyma.)

The cornea normally contains more riboflavin even than the retina, which has a much higher rate of metabolism. When the cornea isn't able to get enough oxygen from the air for its needs (and if riboflavin is deficient, its need for oxygen is increased), surrounding blood vessels at first dilate in response to the diffusing lactic acid, to increase the blood supply to the edges of the cornea. If the problem is prolonged, the conjuctiva becomes chronically blood-shot, hyperemic, and larger more visible blood vessels grow, surrounding the cornea, or even invading the cornea. Many people, especially women, experienced problems of this sort from wearing contact lenses, especially when the lenses were made of materials very impermeable to oxygen (Dumbleton, et al., 2006).

Sunlight, and mechanical obstruction of the cornea, produce very localized effects, but those local effects are more likely to be harmful when there is a systemic nutritional deficiency or excess of estrogen. When the systemic problem is very severe, the cheeks, nose, and eyes might not be the first tissues to experience a functional disturbance.

The mitochondrial inhibition produced by the action of the parasympathetic nervous system (occurring in simple blushing) can occur wherever those nerves act, and blood vessels in all parts of the body are responsive to the acetylcholine secreted by those nerves. Sleep typically involves a shift of dominance in the autonomic nervous system toward the parasympathetic nerves, with vasodilation. Nosebleeds, especially in children, commonly occur during sleep (Jarjour & Jarjour, 2005: high incidence in sleep, and association with migraine).

A 3 year-old child who had been having an average of 2 nosebleeds every day, during a nap and at night, for several months, also had an extreme behavior problem. He became angry and sometimes violent when he went a little longer than normal between meals. After an oral dose of about ten milligrams of riboflavin, he was able to sleep without having another recurrence of the nosebleeds, and his tantrums became rare. Apparently, the nerve-regulated vasodilation produced by sleep, combined with a riboflavin deficiency, had been enough to produce nosebleeds. The energy deficit resulting from a systemic riboflavin deficiency had probably been causing him to be abnormally sensitive to glycogen depletion, producing sudden anger. In another individual, the energy problem might have taken the form of a memory problem, or of a hemorrhage in the brain or other essential organ.

A 37 year old slightly alcoholic man with a bright red nose and cheeks was an amateur fiction writer, but he was having trouble with his memory for words, and for everyday events. Even

conversationally, he had to struggle for relatively familiar words. On the suggestion that riboflavin might help his memory, by allowing his brain cells to use oxygen more efficiently, he had his doctor give him an intravenous injection of B vitamins. When I saw him the next day, his conversation was perfectly fluent, and he obviously had easy access to a good vocabulary. Just as noticeable was the normal color of his nose and cheeks. For a week, he had a daily injection of the B vitamins, and his nose color and vocabulary stayed normal. But on the weekend, after not having the shots for two days, his nose and cheeks were again maraschino cherry red, and his speech was halting, as he struggled for words. He forgot the whole episode, and neglected to return to the doctor for more of the vitamin injections. Ten years later, he had developed a medium-sized potato nose, and had his heart valves replaced.

His vitamin requirements were apparently abnormally high. At first, the problems resulting from damaged mitochondria seem mostly functional (flushing, mood, memory problems, etc.) and variable, but chronically disturbed functions lead to structural, anatomical changes, as prolonged stimulation alters tissue maintenance and growth.

Abram Hoffer, who had been treating schizophrenia and senile dementia with niacin, accidentally discovered that it cured his bleeding gums. That led to its use to treat heart disease.

The "orthomolecular" ideas of Hoffer and Linus Pauling were developed in a context of biochemistry governed by genetics, molecular biology, in which the goal was to provide a chemical that was lacking because of a genetic defect in metabolism. Their idea of using nutrients as drugs has led to many unphysiological practices, in which an isolated nutrient is supposed to have a drug-like action, and if in isolation it doesn't act like a drug, then it should be used only according to the normal genetically determined nutritional requirement.

But in reality, nutritional requirements are strongly influenced by history and present circumstances. For example, when corneal mitochondria have been damaged by riboflavin deficiency, they have been found to subsequently require more than the normal amount of the vitamin to function properly. And the presence of a certain amount of one nutrient often increases or decreases the amount of other nutrients needed.

When the interactions among energy expenditure and energy production, and cellular activation and cellular inhibition, are taken into account, then it's clear that any particular problem is likely to have many causes and many factors that could contribute to a cure.

Lactate, glutamate, ammonium, nitric oxide, quinolinate, estrogen, histamine, aminolevulinate, porphyrin, ultraviolet light, polyunsaturated fatty acids and endotoxin contribute to excitatory and excitotoxic processes, vasodilation, angioneogenesis, and fibrosis.

Carbon dioxide, glycine, GABA, saturated fatty acids (for example, Nanji, et al., 1997), vitamin K, coenzyme Q10, niacinamide, magnesium, red light, thyroid hormone, progesterone, testosterone, and pregnenolone are factors that can be increased to protect against inappropriate cellular excitation.

All of the nutritional factors that participate in mitochondrial respiration contribute to maintaining a balance between excessive excitation and protective inhibition. Riboflavin, coenzyme Q10, vitamin K, niacinamide, thiamine, and selenium are the nutrients that most directly relate to mitochondrial energy production.

Coffee is often avoided by people with rosacea, but it is a very good source of niacin and magnesium, and caffeine has some of the same cell-protective functions as niacinamide.

People suffering from rosacea have been found to be more likely than average to have suffered from styes in childhood, to have varicose veins and spider veins, and to suffer from migraines and depression.

Hypothyroidism has been identified as a factor in all of those. Good thyroid function is necessary for resistance to bacterial infection, for regulation of blood sugar, neurotransmitters, and hormones related to mood, and for the formation of progesterone. Progesterone regulates smooth muscle tone, including the walls of veins, so that a deficiency allows veins to enlarge. It also prevents overgrowth of fibrotic tissue, and in some contexts may inhibit angioneogenesis.

GABA itself tends to raise body temperature (Ishiwata, et al., 2005), by controlling vasodilation, and the factors such as progesterone which protect mitochondrial energy production are also thermogenic, supporting the GABA system. Flushing, both by directly causing heat loss and by reducing mitochondrial energy production, tends to lower body temperature.

The sun-damaged areas in rosacea can be directly provided with some of the protective factors by applying them topically. In the same way that topical lactate can cause vasodilation and disturbed energy metabolism (Rendl, et al., 2001), topical niacinamide, progesterone, vitamin K, and coenzyme Q10 can improve the metabolism and function of the local tissues. Riboflavin can probably be useful when applied topically, but because of its extreme sensitivity to light, it should usually be used only internally, unless the treated skin is covered to prevent exposure to light. Topically applied caffeine, even after sun exposure, can reduce local tissue damage (Koo, et al., 2007). Aspirin and saturated fats can also be protective when applied topically.

Some of the benefit from antibiotics probably results from the reduced endotoxin stress when intestinal bacteria are suppressed. However, antibiotics can kill the intestinal bacteria that produce vitamin K, so it's important to include that in the diet when antibiotics are used.

Some fibers, such as raw carrots, that are effective for lowering endotoxin absorption also contain natural antibiotics, so regular use of carrots should be balanced by occasional supplementation with vitamin K, or by occasionally eating liver or broccoli.

Abram Hoffer's research was instrumental in getting niacin recognized as a heart protective drug, but nearly everyone who prescribes it does so to lower blood lipids. That wasn't Hoffer's understanding of its function. He thought it acted directly on blood vessels to protect their integrity. During his studies of its effects on heart disease, he saw that it also lowered cancer mortality, and so began treating cancer patients with it, with considerable success, but there was no medical cliché that could allow the profession to follow in that direction.

The arguments I have outlined for considering rosacea to be essentially a problem of metabolic energy, and the mechanisms that I mention for restoring mitochondrial functions, might seem more complex than Hoffer's orthomolecular views. However, this approach is actually much simpler conceptually than any of the ideologies of drug treatment. It simply points out that certain excitatory factors can interfere with energy production, and that there are opposing "inhibitory" factors that can restore energy efficiency. Sometimes, using just one or two of the factors can be curative.

Because mitochondrial respiration is very similar in every kind of tissue, a physiological view of rosacea could incline us toward considering the effects of these metabolic factors in other organs during stress and aging--what would the analogous condition of rosacea and rhinophyma be in the brain, heart, liver, or kidney?

Invest Ophthalmol Vis Sci. 1991 Jun;32(7):1981-5. **Analysis of flavins in ocular tissues of the rabbit**. Batey DW, Eckhert CD. Riboflavin is the precursor of flavin mononucleotide (FMN) and flavin adenine dinucleotide (FAD), coenzymes required for the activity of flavoenzymes involved in the transfer of electrons in oxidation-reduction reactions. Flavins are light sensitive and rapidly degrade when exposed to light in the near ultraviolet and visible wavelengths. Some of the byproducts of flavin photodegradation are toxic. A quantitative survey of flavins in rabbit ocular tissues is reported. Adult male Dutch-Belt Rabbits were fed purified diets containing 3, 30, or 300 mg riboflavin/kg for 1 month. A method of aqueous extraction and high-performance liquid chromatography with fluorescence detection was used to measure riboflavin, FMN, and FAD in cornea, lens cortex, lens nucleus, retina, and blood. The retina contained the highest flavin concentration. In all tissues, the primary flavin was FAD followed by FMN and riboflavin. The highest concentration of riboflavin occurred in the cornea followed by the retina, lens cortex, and lens nucleus. A trend toward increasing concentrations of riboflavin occurred in the retina and blood in response to excess dietary riboflavin, but the concentration changes were not statistically significant. The highest concentration of FAD and FMN occurred in the retina followed by the

cornea and the lens cortex and nucleus. The relative contribution of riboflavin, FMN, and FAD to the total flavin pool was markedly different in the various tissues of the eye. The proportion of tissue flavins present as riboflavin decreased from anterior to posterior. It was highest in the cornea followed by lens and retina. The pattern of distribution for FMN was: cornea greater than retina greater than lens cortex and nucleus.

Sex hormones appear to play an important role as modulators of autoimmune disease onset/perpetuation. Steroid hormones are implicated in the immune response, with estrogens as enhancers at least of humoral immunity, and androgens and progesterone (and glucocorticoids) as natural immune suppressors. Serum levels of estrogens have been found to be normal in rheumatoid arthritis (RA) patients. Synovial fluid levels (SF) of proinflammatory estrogens relative to androgens are significantly elevated in both male and female RA patients as compared to controls, which is most probably due to an increase in local aromatase activity. Thus, available steroid pre-hormones are rapidly converted to proinflammatory estrogens in the synovial tissue in the presence of inflammatory cytokines (i.e. TNF alpha, IL-1, IL-6). The increased estrogen concentrations observed in RA SF of both sexes are characterized mainly by the hydroxylated forms, in particular 16 alpha-hydroxyestrone, showing a mitogenic stimulating role. Indeed, recent studies by us indicate that 17-beta estradiol (E2) clearly enhanced the expression of markers of cell growth and proliferation, whereas testosterone (T) induced an increase in markers indicating DNA damage and apoptosis. In particular, our data further shows that the enhancing role of estrogens on the immune/inflammatory response is exerted by activating the NFkB complex. In conclusion, locally increased estrogens may exert activating effects on synovial cell proliferation, including macrophages and fibroblasts, suggesting new roles for estrogens in RA.

Results from the first National Health and Nutrition Examination Survey, 1971-1974.** Engel A, Johnson ML, Haynes SG. The dermatologic component of the first National Health and Nutrition Examination Survey (N = 20,637), conducted from 1971 through 1974, documented the deleterious effect of ultraviolet radiation on selected skin and eye conditions. Actinic skin damage was more frequent in white men with high as compared with low sunlight exposure, 36.7% vs 23.3%, respectively. Among white women, the corresponding figures were 34.1% vs 18.6%, respectively. Actinic damage was found more often in individuals with light eye color. Basal cell epitheliomas were found in 11.3% of white men aged 65 to 74 years who had severely actinic-damaged skin as compared with 1.0% of those with undamaged skin. Sunlight exposure was positively associated with localized hypomelanism, localized hypermelanism, seborrheic keratoses, senile lentigines, freckles, acne rosacea, spider nevi, varicose veins, venus star, dry skin, wrinkled skin, pterygia, arcus senilis, and a variety of minor oral lesions of the tongue, palate, and buccal mucosa. These findings suggest that a large number of dermatologic conditions, which may in part result from overexposure to sunlight, may be preventable.

Circ Res. 1992 Nov;71(5):1268-76. **Interferon-gamma and tumor necrosis factor synergize to induce nitric oxide production and inhibit mitochondrial respiration in vascular smooth muscle cells.** Geng Y, Hansson GK, Holme E. "Nitric oxide (NO) is an important signal substance in cell-cell communication and can induce relaxation of blood vessels by activating guanylate cyclase in smooth muscle cells (SMCs)." "It was recently shown that SMCs may themselves produce NO or an NO-related compound. We have studied NO production and its effects on energy metabolism in cultured rat aortic smooth muscle cells. It was observed that the cytokines, interferon-gamma and tumor necrosis factor-alpha, synergistically induced an arginine-dependent production of NO in these cells. This

was associated with an inhibition of complex I (NADH: ubiquinone oxidoreductase) and complex II (succinate: ubiquinone oxidoreductase) activities of the mitochondrial respiratory chain, suggesting that NO blocks mitochondrial respiration in these cells. Lactate accumulated in the media of the cells, implying an increased anaerobic glycolysis, but there was no reduction of viability. An NO-dependent inhibition of mitochondrial respiration and a switch to anaerobic glycolysis would reduce energy production of the SMCs. This would in turn reduce the contractile capacity of the cell and might represent another NO-dependent vasodilatory mechanism."

"Previous research has established that 4-hydroxy-2-nonenal (HNE), a highly toxic product of lipid peroxidation, is a potent inhibitor of mitochondrial respiration. HNE exerts its effects on respiration by inhibiting alpha-ketoglutarate dehydrogenase (KGDH). Because of the central role of KGDH in metabolism and emerging evidence that free radicals contribute to mitochondrial dysfunction associated with numerous diseases, it is of great interest to further characterize the mechanism of inhibition." "These results therefore identify a potential mechanism whereby free radical production and subsequent lipid peroxidation lead to specific modification of KGDH and PDH and inhibition of NADH-linked mitochondrial respiration."

Biochemistry. 1998 Jan 13;37(2):552-7. **Inhibition of NADH-linked mitochondrial respiration by 4-hydroxy-2-nonenal.** Humphries KM, Yoo Y, Szweda LI. During the progression of certain degenerative conditions, including myocardial ischemia-reperfusion injury, mitochondria are a source of increased free-radical generation and exhibit declines in respiratory function(s). It has therefore been suggested that oxidative damage to mitochondrial components plays a critical role in the pathology of these processes. Polyunsaturated fatty acids of membrane lipids are prime molecular targets of free-radical damage. A major product of lipid peroxidation, 4-hydroxy-2-nonenal (HNE), is highly cytotoxic and can readily react with and damage protein. In this study, the effects of HNE on intact cardiac mitochondria were investigated to gain insight into potential mechanisms by which free radicals mediate mitochondrial dysfunction. Exposure of mitochondria to micromolar concentrations of HNE caused rapid declines in NADH-linked but not succinate-linked state 3 and uncoupled respiration. The activity of complex I was unaffected by HNE under the conditions of our experiments. Loss of respiratory activity reflected the inability of HNE-treated mitochondria to meet NADH demand during maximum rates of O2 consumption. HNE exerted its effects on intact mitochondria by inactivating alpha-ketoglutarate dehydrogenase. These results therefore identify a potentially important mechanism by which free radicals bring about declines in mitochondrial respiration.

Rosacea is a chronic disorder characterized by hypersensitivity of the facial vasculature, presenting with intense flushing eventually leading to chronic erythema and telangiectasia. Although the precise aetiology of rosacea is not known, numerous associations with inflammatory gastrointestinal tract disorders have been reported. Furthermore, substance P-immunoreactive neurones occur in considerably greater numbers in tissue surrounding affected blood vessels suggesting involvement of neurogenic inflammation and moreover plasma kallikrein-kinin activation is consistently found in patients. In this report, a patient without digestive tract disease is described, who experienced complete remission of rosacea symptoms following ingestion of a material intended to sweep through the digestive tract and reduce transit time below 30 h. It is possible that intestinal bacteria are capable of plasma kallikrein-kinin activation and that flushing symptoms and the development of other characteristic features of rosacea result from frequent episodes of neurogenic inflammation caused by bradykinin-induced hypersensitization of facial afferent neurones. The possible relevance of this hypothesis to other conditions featuring afferent hypersensitivity, such as fibromyalgia, is considered.

Milk in context: allergies, ecology, and some myths

Food allergies are becoming much more common in recent decades, especially in industrialized countries. Most attention has been given to theories about changes in people, such as the reduction in infectious diseases and parasites, or vitamin D deficiency, or harmful effects from vaccinations, and little attention has been given to degradation of the food supply.

Our food cultures, like linguistic and moral cultures, give us some assumptions or theories about the way the world should be, and if these beliefs aren't questioned and tested, they can permeate the culture of science, turning the research process into a rationalization of accepted opinions.

In general, those who pay for research are those with an investment in or commitment to the preservation and expansion of the existing systems of production and distribution. Cheap mass production, durability and long shelf-life are more important than the effects of foods on health. The biggest industries are usually able to keep public attention away from the harm they do.

The historical economic importance of cereals and beans is reflected in the nutritional and biochemical research literature, which has paid relatively little attention to basic questions about human adaptation to the ecosystems. From the early petrochemical "Green Revolution" to the contemporary imposition of genetically altered seeds, the accumulated economic power of the food industry has taken control of the food culture.

In evaluating each research publication relating to nutrition and health, we should ask what alternative possibilities are being neglected, for "practical" reasons, cultural preferences, and business interests.

Some people with an ecological concern have argued that grains and beans can most economically provide the proteins and calories that people need, but good nutrition involves much more than the essential nutrients.

"Efficient" industrial agriculture has been concerned with cheaply producing those important nutrients, and their critics have focussed on their use of toxic chemicals, on the social damage they produce, the degradation of the soil, the toxic effects of genetic modification, their unsustainable use of petroleum, and occasionally on the lower nutritional value of chemically stimulated crops.

I think far too little attention is being given to the effects of abnormal and stressful growth conditions on the plants' natural defense systems. Plants normally synthesize some toxins and inhibitors of digestive enzymes to discourage attacks by bacteria, fungi, insects, and other predators. When a plant is injured or otherwise stressed, it produces more of the defensive substances, and very often they communicate their stress to other plants, and the resulting physiological changes can cause changes in seeds that affect the resistance of the progeny. (Agrawal, 2001)

One of many substances produced by plants in response to injury is chitinase, an enzyme that breaks down chitin, a polysaccharide that is a structural component of fungi and insects. Chitinase, which is produced by bacteria and humans, as well as by plants and other organisms, is involved in developmental processes as well as in the innate immune system. In plants, the enzyme is induced by ethylene and salicylate, in animals by estrogen, light damage, and infections, and can be demonstrated in polyps and cancers.

The two main classes of plant allergens are the stress-induced chitinases, and seed storage proteins, such as gluten. The chitinase allergens are responsible for reactions to latex (which is secreted by rubber trees in reaction to a wound), bananas, avocados, many other fruits and vegetables, and some types of wood and other plant materials. Intensive agricultural methods are increasing the formation of the defensive chemicals, and the industrialized crops are responsible for the great majority of the new allergies that have appeared in the last 30 years.

The presence of the chitinase family of proteins in humans was first discovered in the inflamed asthmatic lung. It was then found at high levels in the uterine endometrium at the time of implantation of the embryo (an inflammation-like situation) and in the uterus during premature labor. Since estrogen treatment is known to increase the incidence of asthma and other inflammations, the appearance of chitinase also in the uterus in estrogen dominated conditions is interesting, especially when the role of estrogen in celiac disease (in effect an allergy to gluten) is considered. Celiac disease is more prevalent among females, and it involves the immunological cross-reaction to an antigen in the estrogen-regulated transglutaminase enzyme and the gluten protein. The (calcium-regulated) transglutaminase enzyme is involved in the cross-linking of proteins in keratinized cells, in fibrotic processes in the liver, and in cancer. (People with celiac disease often suffer from osteoporosis and urinary stone deposition, showing a general problem with calcium regulation.)

This means that estrogen and stress cause the appearance of antigens in the human or animal tissues that are essentially the same as the stress-induced and defensive proteins in plant tissues. A crocodile might experience the same sort of allergic reaction when eating estrogen-treated women and when eating commercial bananas.

The various states of the innate immune system have been neglected by immunologists, for example in relation to organ transplantation. The "major histocompatibility" antigens are matched, but organ transplants still sometimes fail. A study found that the livers from young men had a high survival rate when transplanted into either men or women, but the livers of older women donors were rejected at a high rate when transplanted into either men or women. Exposure to estrogen increases intracellular calcium and the unsaturation of fatty acids in tissue lipids, and the expression of enzymes such as chitinase and transglutaminase, and the various enzymes in the structure-sensitive estrogen-controlled metabolic pathways.

Estrogen's actions are closely and pervasively involved with the regulation of calcium, and these changes affect the basic tissue structures and processes that constitute the innate immune system. Estrogen's effect in increasing susceptibility to "autoimmune" diseases hasn't yet been recognized by mainstream medicine.

The chemist Norman Pirie argued convincingly that leaf protein had much higher nutritional value than grain and bean proteins, and that it had the potential to be much more efficient economically, if it could be separated from the less desirable components of leaves.

The amino acid composition and nutritional value of leaf protein is similar to milk protein, which is understandable since cows produce milk from the amino acids produced in their rumens by bacteria digesting the leaves the cows have eaten. The bacteria perform the refining processes that Pirie believed could be done technologically, and they also degrade or detoxify the major toxins and allergens.

The nutrients produced in the cow's rumen are selectively absorbed into the cow's bloodstream, where the liver can further filter out any toxins before the amino acids and other nutrients are absorbed by the udder to be synthesized into milk. If cows are fed extremely bad diets, for example with a very large amount of grain, the filtering process is less perfect, and some allergens can reach the milk, but since sick cows are less profitable than healthy cows, dairies usually feed their cows fairly well.

In a recent study of 69,796 hospitalized newborns, a diagnosis of cow's milk allergy was made in 0.21% of them. Among those whose birthweight had been less than a kilogram, 0.35%

of them were diagnosed with the milk allergy. Gastrointestinal symptoms were the main reason for the diagnosis, but a challenge test to confirm the diagnosis was used in only 15% of the participating hospitals, and a lymphocyte stimulation test was used in only 5.5% of them (Miyazawa, et al., 2009). There are many publications about milk allergies, but they generally involve a small group of patients, and the tests they use are rarely evaluated on healthy control subjects.

Several surveys have found that of children who have a diagnosed milk allergy, about 2/3 of them grow out of the allergy.

People who have told me that they have had digestive problems with milk have sometimes found that a different brand of milk doesn't cause any problem.

Milk with reduced fat content is required by US law to have vitamins D and A added. The vehicle used in the vitamin preparation, and the industrial contaminants in the "pure" vitamins themselves, are possible sources of allergens in commercial milk, so whole milk is the most likely to be free of allergens.

A thickening agent commonly used in milk products, carrageenan, is a powerful allergen that can cause a "pseudo-latex allergy" (Tarlo, et al., 1995). It is a sulfated polysaccharide, structurally similar to heparin. There are good reasons to think that its toxic effects are the result of disturbance of calcium metabolism (see for example Abdullahi, et al., 1975; Halici, et al., 2008; Janaswamy and Chandrasekaran, 2008).

Besides the idea of milk allergy, the most common reason for avoiding milk is the belief that the genes of some ethnic groups cause them to lack the enzyme, lactase, needed to digest milk sugar, lactose, and that this causes lactose intolerance, resulting in gas or diarrhea when milk is consumed. Tests have been reported in which a glass of milk will cause the lactase deficient people to have abdominal pain. However, when intolerant people have been tested, using milk without lactose for comparison, there were no differences between those receiving milk with lactose or without it. The "intolerant" people consistently tolerate having a glass with each meal.

When a group of lactase deficient people have been given some milk every day for a few weeks, they have adapted, for example with tests showing that much less hydrogen gas was produced from lactose by intestinal bacteria after they had adapted (Pribila, et al., 2000).

Bacterial overgrowth in the small intestine can be caused by hypothyroidism (Lauritano, et al., 2007), and the substances produced by these bacteria can damage the lining of the small intestine, causing the loss of lactase enzymes (Walshe, et al., 1990).

Another hormonal condition that probably contributes to lactase deficiency is progesterone deficiency, since a synthetic progestin has been found to increase the enzyme (Nagpaul, et al., 1990). The particular progestin they used lacks many of progesterone's effects, but it does protect against some kinds of stress, including high estrogen and cortisol. This suggests that stress, with its increased ratio of estrogen and cortisol to progesterone, might commonly cause the enzyme to decrease.

Two other ideas that sometimes cause people to avoid drinking milk and eating cheese are that they are "fattening foods," and that the high calcium content could contribute to hardening of the arteries.

When I traveled around Europe in 1968, I noticed that milk and cheese were hard to find in the Slavic countries, and that many people were fat. When I crossed from Russia into Finland, I noticed there were many stores selling a variety of cheeses, and the people were generally slender. When I lived in Mexico in the 1960s, good milk was hard to find in the cities and towns, and most women had fat hips and short legs. Twenty years later, when good milk was available in all the cites, there were many more slender women, and the young people on average had much longer legs. The changes I noticed there reminded me of the differences I had seen between Moscow and Helsinki, and I suspect that the differences in calcium intake were partly responsible for the changes of physique.

In recent years there have been studies showing that regular milk drinkers are less fat than people who don't drink it. Although the high

quality protein and saturated fat undoubtedly contribute to milk's anti-obesity effect, the high calcium content is probably the main factor.

The parathyroid hormone (PTH) is an important regulator of calcium metabolism. If dietary calcium isn't sufficient, causing blood calcium to decrease, the PTH increases, and removes calcium from bones to maintain a normal amount in the blood. PTH has many other effects, contributing to inflammation, calcification of soft tissues, and decreased respiratory energy production.

When there is adequate calcium, vitamin D, and magnesium in the diet, PTH is kept to a minimum. When PTH is kept low, cells increase their formation of the uncoupling proteins, that cause mitochondria to use energy at a higher rate, and this is associated with decreased activity of the fatty acid synthase enzymes.

These changes are clearly related to the anti-obesity effect of calcium, but those enzymes are important for many other problems.

The "metabolic syndrome," that involves diabetes, hypertension, and obesity, is associated with high PTH (Ahlström, et al., 2009; Hjelmesaeth, et al., 2009).

Alzheimer's disease involves decreased mitochondrial activity and low levels of the uncoupling proteins. There is evidence that milk drinkers are protected against dementia (Yamada, et al., 2003). Cancer involves increased activity of the fatty acid synthase enzymes. Increased calcium consumption beneficially affects both sets of enzymes, uncoupling proteins and fatty acid synthase.

Multiple sclerosis relapses consistently occur at times of high PTH, and remissions consistently occur at times of low PTH (Soilu-Hänninen, et al., 3008). PTH increases the activity of nitric oxide synthase, and nitric oxide is a factor in the vascular leakiness that is so important in MS.

There are components of milk that might protect against tooth decay by inhibiting the binding of bacteria to teeth (Danielsson, et al., 2009).

David McCarron has published a large amount of evidence showing how calcium deficiency contributes to high blood pressure. The chronic elevation of PTH caused by calcium deficiency causes the heart and blood vessels to retain calcium, making them unable to relax fully.

Intravenous infusion of calcium can relax blood vessels and improve heart function. The suppression of PTH is probably the main mechanism.

PTH (like estrogen) causes mast cells to release promoters of inflammation, including histamine and serotonin. Serotonin and nitric oxide contribute to increasing PTH secretion.

Removal of the parathyroid gland has reduced heart problems and mortality (Costa-Hong, et al., 2007) and insomnia (Esposito, et al., 2008; Sabbatini, et al., 2002) in people with kidney disease and excess PTH.

Increased carbon dioxide, for example when adapted to high altitude, can greatly decrease PTH. Frequent, but smaller, meals can reduce PTH.

Cancer cells often secrete PTH and related proteins with similar effects on calcium, and the PTH stimulates the growth and invasiveness of prostate cancer (DaSilva, et al., 2009) cells, and seems to be as closely involved with breast cancer. The PTH-related protein is associated with calcification in breast cancer (Kanbara, et al., 1994). Microscopic calcium crystals themselve produce inflammation (Denko and Whitehouse, 1976).

Besides being an ecologically favorable source of calcium, protein, sugar, and fat, the composition of milk causes it to be digested efficiently, supporting the growth of bacteria that are relatively safe for the intestine and liver, and reducing the absorption of endotoxin.

Dividing any food into smaller meals can lower the PTH, and milk is a convenient food to use in small amounts and frequently.

Some amino acids directly stimulate insulin secretion, decreasing blood sugar and leading to the secretion of cortisol in reaction to the depression of blood glucose. The presence of lactose in milk, and of fat, to slow absorption of the amino acids, helps to minimize the secretion of cortisol. The main protein of milk, casein, seems to have some direct antistress effects (Biswas, et al., 2003).

Since milk's primary biological function is to support the growth of a young animal, some of its features make it inappropriate as a sole food for an adult. To support cell division and growth, the methionine and tryptophan content of milk is higher than would be optimal for an adult animal, and the phosphate might be slightly more than needed, in relation to the calcium. Since the fetus stores a large amount of iron during gestation, the iron content of milk is low, and when a young animal has used the stored iron, its continuing growth requires more iron than milk provides. However, for an adult, the low iron content of milk and cheese makes these foods useful for preventing the iron overload that often contributes to the degenerative diseases.

Combining milk and cheese with fruits adds to the antistress effect. The additional sugar and potassium and other minerals allow the milk protein to be used more efficiently, by moderating the secretion of cortisol, and helping to inhibit the secretion of PTH.

Substances such as PTH, nitric oxide, serotonin, cortisol, aldosterone, estrogen, thyroid stimulating hormone, and prolactin have regulatory and adaptive functions that are essential, but that ideally should act only intermittently, producing changes that are needed momentarily. When the environment is too stressful, or when nutrition isn't adequate, the organism may be unable to mobilize the opposing and complementary substances to stop their actions. In those situations, it can be therapeutic to use some of the nutrients as supplements. Calcium carbonate (eggshell or oyster shell, for example) and vitamins D and K, can sometimes produce quick antistress effects, alleviating insomnia, hypertension, edema, inflammations and allergies, etc., but the regular use of milk and cheese can prevent

To the wicked, everything serves as pretext. – Voltaire

Inflammation, endotoxin, estrogen, and other problems

Over the last few decades, the meaning of inflammation has changed a little, from being thought of simply as an essential part of the immune reaction, to being recognized as something that can interfere with the immune system, and that contributes to chronic disease and degeneration.

Many components of the inflammatory reaction have been identified lately, but the way those fit into the context of the whole organism still isn't clear.

Many of the "evolutionary interpretations" of particular biological features are just words, empty speculations that can't be tested. (Selective breeding experiments and comparative physiology can provide some basis for arguments about the evolution of the immune system, but the people who created the "big picture" weren't burdened by a need for detailed evidence.)

Developmental processes, however, have been studied in great detail, and as information accumulates, it is becoming clear that the traditional view of inflammation has little to do with reality. When inflammation is "explained" as something that evolved to protect the organism against infection, people will be taught that theory, and will feel no need to think about the subject again.

With the newer realization that inflammation can lead to cancer, heart disease, diabetes, dementia, and other degenerative processes, the logical seeming course of action for people taught the traditional "evolutionary" view of inflammation has been to look for the infectious organism causing the problem.

But if we put inflammation into the developmental context, it is immediately clear that infectious agents are just one of the many factors that we interact with and that can be involved in the inflammatory and degenerative processes. Nutrition, toxins, environmental stresses, and biological cycles influence the way we react to infectious organisms, and even in the absence of virulent organisms, can cause inflammation and degeneration. In the uterus and ovary, for example, inflammatory and degenerative changes are part of normal functioning.

In those organs, the cyclic changes in structure are orchestrated to a monthly rhythm that makes them very obvious. But in other organs, such as the adrenal cortex, the intestinal epithelium, the liver, and the skin, there is a continuous process of renewal (and degeneration) of cells that is fairly well known, despite the dogmatists who want to cling to the "Hayflick limit," that denies the existence of a flowing renewal of cells in every organ, or that insists that no renewal is possible after 50 divisions of a cell line. Cell renewal occurs even in the brain and the heart. The Hayflick doctrine was plausible to people who were committed to a Weismannist view of genetics and development, a view that radically denied the role of organismic and environmental interactions in development.

Cells that are well insulated from the environment can live for a very long time, but cells that directly contact the environment, i.e., the skin and the intestinal epithelium, divide rapidly, and are shed.

When stimulation is great, and energy supply is weak, a cell will either adapt to the conditions, sometimes increasing its rate of division, or die. Nerve cells can protect themselves by becoming insensitive to stimulation; in some cases, the

stress-induced loss of its axon can probably turn a nerve cell into a resting, or stem, cell.

The dissolution of a cell releases its materials in different ways, according to the conditions that caused it to die. Sometimes it releases histamine and other substances that can increase blood flow in nearby capillaries, but under other conditions it can liquefy without causing much change in its environment. When a significant amount of cellular debris accumulates in an area, wandering cells sense it, and depending on the nature of the injury, they may simply remove the debris, or stay and adapt, forming part of a repair structure.

Proteolytic enzymes and nucleases can decompose most of the structural proteins and nucleic acids, but the lipases that act on the dead cell's structural lipids release a variety of modified phospholipids, fatty acids, and cholesterol, with considerable biological activity or significance. These substances appear with regularity when cells are being damaged, and they are the most important class of signals acting on the immune system. Oxidized phospholipids can cause other cells to form a variety of substances that amplify the alarm signal (e.g., Kadl, et al., 2002). Their importance justifies the view of J. Cunliffe and P. Matzinger, that the immune system is actually a system of structural development and maintenance, and that its role in killing alien organisms is triggered when tissue damage releases our intrinsic signal substances.

Polyunsaturated fatty acids, derived from foods, have a special role in the immune system, intensifying the effects of stress (cholesterol newsletter, September, 2005) in killing lymphocytes, and blocking the proliferative response of thymic cells (Rotondo, et al., 1994). They tend to shift immune functions from cellular immunity to humoral (antibody) immunity, and this pattern predisposes to autoimmunity. They are probably directly toxic to the liver (Ritskes-Hoitinga, 1998). DHA increases the leakiness of the bowel, allowing more endotoxin to enter the circulation (Roig-Perez, et al., 2004).

When cells have enough glucose, oxygen, and thyroid hormone, and aren't being over-stimulated, energy consumption can be uncoupled from the formation of ATP. This allows the mitochondria to devote more energy to the production of the material needed for synthesizing cholesterol and its derivatives, pregnenolone, progesterone, and DHEA, and to form carbon dioxide at a high rate. Uncoupling helps to lower the formation of inflammatory cytokines (Horvath, et al., 2003). A chronically "uncoupled" metabolic state has been associated with longevity (Speakman, et al., 2004). The rate of cholesterol production, and the amount in circulation, tend to be inversely related to systemic inflammation. All of the types of lipoprotein absorb, bind, and help to eliminate endotoxin, for example. Carbon dioxide and the major steroids stabilize cells against excessive stimulation, and protect the cell structure.

Bacteria and plants produce a variety of lipids that serve some purposes analogous to our cholesterol and phospholipids. Some of the common intestinal bacteria produce a molecule containing amino sugars and fatty acids (lipopolysaccharide, LPS), that's called endotoxin. The "endo" root distinguishes it from the "exotoxins" secreted by some bacteria, because the endotoxin is a structural part of the bacterium, that protects the bacterium against some of the exotoxins produced by other microorganisms. Normally, our intestine and liver destroy most of the LPS endotoxin before it reaches the general circulation. The bile acids, a major end product of cholesterol, have a detergent action in the intestine that usually keeps endotoxin in solution, away from the absorptive surfaces of the intestine. If the flow of bile is obstructed, endotoxin is allowed to enter the system (Bertok, 2004). Estrogen can inhibit the flow of bile (Stieger, et al., 2000). A mucus lining is part of the protective barrier, but the microscopic integrity of the intestinal cells themselves finally regulates the passage of materials into the blood and lymphatic vessels.

The barrier function of the intestine is weakened by poisons, malnutrition, and the reduced circulation that can result from stress. Estrogens, such as oral contraceptives or Premarin, can cause colitis by shutting off the blood supply (Gurbuz, et al., 1994; Deana and Dean, 1995).

When our cells are exposed to LPS, they produce many of the same reactions that they

would produce in response to our endogenous phospholipids. The major proteins that interact with cholesterol contain lipophilic regions called beta sheets, in which a relatively flat surface is formed by parallel strands of the protein. LPS contains a group of fatty acids bound together by the polysaccharide, that strongly binds to these proteins.

The alarm reaction produced either by damage of some of our own tissue or by the entrance of LPS into the circulation can, under ideal circumstances, lead to a series of protective and defensive reactions, that resolve the problem. The production of steroids is increased, and, early in life, the liberation of fatty acids itself can contribute to the antiinflammatory processes that restore the barrier function and energy production. But when the endogenous omega-9 fatty acids have been thoroughly displaced by dietary omega-6 and omega-3 fatty acids, the systemic release of fatty acids becomes an amplifier of the stress state initiated by injury or other stress. The liver, for example, decreases its detoxification of estrogen in the presence of polyunsaturated fatty acids.

In the ovary and uterus, the healthy alternation of excitation and quiescence usually continues for many years, and in rodents it often ends in a state of "persistent estrus," in which the excitatory state can't be terminated in the usual way, by the production of progesterone. In humans, menopause is analogous, because the excitatory FSH hormone from the pituitary becomes excessive, with the ovary continuing to produce estrogen but failing to produce progesterone, sometimes with the pituitary failing to shift from FSH to LH. In rodents, it's recognized that persistent estrus is caused by chronically elevated estrogen, but in humans there has been tremendous resistance to the recognition of estrogen's central role in menopause and senescence. An excess of the basic promoter of inflammation, serotonin, which is closely associated with estrogen's influence, can have similar effects on the reproductive cycle (Cooper, et al., 1986). The industry has devoted the necessary funding to making the easily manipulated medical culture, and the public, believe the opposite, i.e., that reproductive aging is mainly caused by estrogen deficiency.

The liver, besides its important role in keeping endotoxin from reaching the circulation, normally "destroys" all of the estrogen that reaches it, that is, it makes it water soluble so that it will be excreted in the urine or bile, rather than being retained by cells. But in malnutrition, hypothyroidism, or stress, the liver allows estrogen to pass through without being completely inactivated. M.S. Biskind and G.R. Biskind (1941, 1946) showed that the B vitamins were crucial for estrogen elimination, and others around the same time demonstrated that toxins, protein deficiency, hypothyroidism, and even hyperestrogenism itself tended to reduce the liver's ability to detoxify estrogen. Endotoxin's inhibition of this detoxifying system (Banhegyi, et al., 1995) is just one of the ways that it increases estrogen systemically.

Estrogen, which was named for a gadfly, is excitatory in all of its biological actions (including nervous excitation and cellular proliferation), and in most tissues this excitatory action has been shown to cause oxidation damage. Many different toxic changes have been produced in the liver by estrogen, but lipid peroxidation can be clearly demonstrated in the liver as an early reaction to subcutaneous estrogen injection (Genc, et al., 1999).

Endotoxin and estrogen interact in many interesting and potentially deadly ways. Both of them activate many of the same alarm systems, including phospholipases, nitric oxide synthase, tumor necrosis factor (TNF), interleukins (including IL-6, according to Bengtsson, et al., 2004), and the enzymes that form prostaglandins from polyunsaturated fatty acids. Estrogen makes the toxic-mediator-producing cells in the liver (Kupffer cells) hypersensitive to LPS--15 times more sensitive than normal (Ikejima, et al., 1998). One way estrogen increases the toxicity of endotoxin is probably by making the intestine more permeable (Enomoto, et al., 1999). The acute phase reaction, a process in which the liver decreases its production of albumin and increases the production of serum amyloids, lipoproteins, and fibrinogen, is promoted by both estrogen and endotoxin. Estrogen (like endotoxin) activates nuclear factor kappa-B (Shyamala and Guiot, 1992; Hamilton, et al., 2003), which activates

cells to produce TNF, nitric oxide, prostaglandins, and interleukins. A long series of observations have indicated that estrogen's main effects begin with redox changes in the mitochondria, and recent evidence (Felty and Roy, 2005) shows that oxidative free radicals produced in the mitochondria by estrogen induce NF kappa-B. Old age is associated with increased activity of NF kappa-B.

Aspirin, increased levels of carbon dioxide (Ni Chonghaile, et al., 2005), and progesterone (Deroo and Archer, 2002; Kelly, et al., 2001; Allport, et al., 2001; van der Burg and van der Saag, 1996; Caldenhoven, et al., 1995) inhibit NF kappa-B, and NF kappa-B inhibits the synthesis of both testosterone (Hong, et al., 2004) and progesterone (Allport, et al., 2001).

The amount of injury needed to increase the endotoxin in the blood can be fairly minor. Two thirds of people having a colonoscopy had a significant increase in endotoxin in their blood, and intense exercise or anxiety will increase it. Endotoxin activates the enzyme that synthesizes estrogen while it decreases the formation of androgen (Christeff, et al., 1992), and this undoubtedly is partly responsible for the large increases in estrogen in both men and women caused by trauma, sickness or excessive fatigue.

The positive interactions among estrogen and endotoxin and NF kappa-B, and their negative interactions with progesterone and testosterone, tend to "stabilize" the inflammatory condition. In a young person, good food, sunlight, and a high altitude can often overcome severe and progressive inflammatory conditions. In an older person, whose tissues contain larger amounts of polyunsaturated fats and their breakdown products, it takes more environmental support to get out of the inflammatory pattern.

Glycine (the main amino acid in gelatin) is an important nutrient with powerful antiinflammatory actions (Zhong, et al., 1999; Wang, et al., 2004). Saturated fatty acids can help to reduce chronic inflammatory states, but it's essential to eliminate as far as possible the unstable polyunsaturated fatty acids, which suppress normal immune functions, besides contributing to the free radical-lipid peroxidation burden. Cholesterol and ATP have been used therapeutically, but ordinarily their synthesis can be increased safely by using a diet that contains a significant amount of ordinary sugar (sucrose, from fruits) when the thyroid function is adequate.

Since vascular leakiness is involved in the inflammatory syndromes, as well as in shock, I think it's reasonable to treat them similarly, keeping in mind the importance of normal blood volume and viscosity. Sodium and sugar help to lower adrenaline, and so they can make a contribution to preventing high blood pressure, while maintaining normal hydration of the blood. Estradiol and cholera toxin, which both increase vascular leakiness, probably exert some of their influence by lowering the osmotic tension of the extracellular fluid (Webster, et al., 1984; Witten and Bradbury, 1951). The enzyme activated by cholera toxin, estrogen, and hypotonic medium in the study by Webster, et al., was ornithine decarboxylase, which produces the polyamines. The polyamines promote cellular proliferation, and promote the actions of the excitotoxic amino acids. Histamine also activates excitotoxicity, and magnesium opposes it.

The inflammatory states that produce the age-related degenerative diseases have many things in common with "pre-eclampsia" or pregnancy toxemia, and the same simple things can usually alleviate both kinds of problem. With aging, intracellular water tends to decrease, as the extracellular water increases (Lesser and Markovsky, 1979), probably because of reduced cellular energy, and increased vascular permeability. When albumin production is adequate, it "binds" sodium, and the combination osmotically increases the ability of the blood to retain water.

Sodium bicarbonate can provide a little extra carbon dioxide, along with the sodium, and its diuretic action is well established, but it works by improving perfusion of the tissues, reducing any abnormal water retention, rather than by causing the kidneys to lose water in unphysiological ways. One of progesterone's important functions is the maintenance of blood volume, and adequate thyroid is essential for preventing hyponatremia (insufficient sodium in the blood, which often occurs in combination with decreased formation of albumin).

Stress, trauma, and shock start an inflammatory process, that can cause progressive damage to the organs, including the liver. Giving progesterone following the injury protects against the increase of TNF, IL-6, and leakage of liver enzymes (Kuebler, et al., 2003). It has similar protective effects in the brain, lungs, and other organs. During the normal menstrual cycle, IL-6 is inversely related to the level of progesterone (Angstwurm, et al., 1997).

The liver's important role in regulating endotoxin and estrogen, and the cascade of inflammatory mediators that can be released as a result of a depression of the liver's function, makes it important to keep the liver in mind, even when the immediate problem seems to be in the brain, the lungs, kidneys, pancreas, blood vessels, heart, eyes, prostate, ovaries, muscles, or any other organ.

Estrogen is obviously part of a primitive repair system, more fundamental or general than its role in reproduction. When a tissue is injured, it forms large amounts of an enzyme, beta-glucuronidase, that removes the water soluble sugar acid, glucuronic acid, from the estrogen glucuronide which circulates harmlessly in the blood after its formation in the liver, and before its elimination in the urine. The injured tissue reverses the inactivation of the estrogen that has occurred in the liver, causing the fat soluble estrogen to remain in the damaged tissue, where it changes the metabolism, activating enzymes that stimulate proliferation and accelerate collagen formation and other processes involved in repair. (Other enzymes, sulfatases and aromatase, contribute to the increase in estrogen in stressed tissues, but beta-glucuronidase has been studied most, because it is very easy to identify.)

These local processes don't depend on liver failure to become active, but in the systemic effects of liver failure they probably play a very important role in amplifying the effects of endotoxin and unprocessed estrogen.

The effects of endotoxin and estrogen on cells are additive, for example in causing vascular leakiness (e.g., Tollan, et al., 1992), even in the brain (Oztas and Kaya, 1998). Dementia, respiratory distress/shock lung, and all of the classical inflammatory conditions, are promoted by the simple process of making capillaries excessively permeable. But the cellular changes that make capillaries leaky, also affect other cells, changing their antigenicity, leading to "autoimmune" processes (Sekigawa, et al., 2004).

Protein deficiency creates an inflammatory state, and since stress causes tissue proteins to be destroyed and converted into sugars and fats, it's common to underestimate the amount of protein needed. One of the functions of sucrose in the diet is to reduce the production of cortisol, and so to spare protein.

Milk has a variety of antiinflammatory functions. Its saturated fats help to prevent oxidation of lipids, including cholesterol. Several of its vitamins, especially vitamins D and K, have antiinflammatory and even antiestrogenic actions. Since the parathyroid hormone (like some of the other pituitary hormones) is pro-inflammatory, a generous supply of calcium is important because it inhibits the secretion of the parathyroid hormone.

Stress activates the endorphin system (partly by increased histamine, according to Kjaer, et al., 1993), and these intrinsic hormones, like morphine and the other opiates, are pro-inflammatory. Both estrogen and endotoxin activate the endorphin system. Excessive exposure to estrogen destroys many of the beta-endorphin nerves in the hypothalamus, resulting in an adaptive hypersensitivity, that maintains a chronic activation of the endorphin sensitive tissues, suppressing progesterone production (Desjardins, 1995).

There are drugs (e.g., naloxone) that can help to block the actions of the endorphins, and since the endorphins inhibit the luteinizing hormone (LH) which promotes the production of progesterone and testosterone, a little naloxone can often restore normal menstrual cycles that have stopped because of stress and excessive exposure to estrogen. Endorphins are probably involved in menopausal flushing, and drugs of the naloxone type have been used to relieve it. But a combination of other antistress factors can do the same.

Salicylic acid, which occurs naturally in many fruits, as well as in aspirin, is unlike the other antiinflammatory drugs so vaguely classified with

it as "nonsteroidal," in having a broad spectrum of antiinflammatory effects, inhibiting the prostaglandins and NF kappa-B, TNF, and IL-6, besides contributing to the inhibition of estrogen synthesis and actions.

Magnesium is lost during stress, and that can lead to destabilization of the mast cells, with increased release of histamine and other promoters of inflammation and excitation. Thyroid hormone helps cells to assimilate and retain magnesium. Estrogen's effect on magnesium seems to be antagonistic (e.g., Muneyyirci-Delale, et al., 1999). Fruits and meats are good sources of magnesium, but coffee and chocolate are among the best sources of it, and the caffeine they contain adds to their antiinflammatory and liver-protective effect (see Sakamoto, et al., 1999).

The saturated fatty acids found in coconut oil inhibit the formation of histamine (Mimura, et al., 1980), as does glucose (Kaneko, et al., 1997), and prevent leakiness of the intestine, protecting the liver from endotoxin (Kono, et al., 2003). Progesterone and testosterone protect against histamine, while estrogen increases its formation and actions. Benadryl (diphenhydramine) protects the liver and other organs from various toxins, and from the toxic effects of histamine.

Thyroid's antiinflammatory function in arthritis and rheumatic conditions has been known for about a century, but there aren't many contemporary publications on its roles in inflammation and degeneration (see Bartalena, et al., 1994; Rittenhouse and Redei, 1997).

TSH, the thyroid stimulating hormone secreted by the pituitary, stimulates some of the inflammatory mediators, and although the definition of the "normal range" has been decreasing, the people I see whose TSH is "normal" aren't as healthy as those whose TSH is well "below normal." Other indicators of adequate thyroid function are needed.

Expired carbon dioxide ("end tidal") is a good indicator, but it's rarely measured. Lactic acid tends to rise in hypothyroidism, so measuring its level in the blood can be helpful. Oxygen consumption, serum cholesterol, daily cycle of temperature and pulse rate, and calorie consumption are good indicators of thyroid function. The inflammatory cytokines can activate the glycolytic enzymes that produce lactic acid (Bauer, et al., 2004), and the thyroid hormone accelerates the oxidation of lactic acid, so I think it's reasonable to think of a higher metabolic rate as a corrective compensation for inflammation, as well as the most important factor in preventing it.

Anyone can measure their calorie consumption with enough accuracy to be useful. Considering that the Criles' measurements of oxygen consumption in the 1930s showed that Americans as a group were extremely hypothyroid, and that other studies done around the same time suggested that nearly half of the population benefitted from supplemental thyroid, we should probably ignore the present "official" recommendations regarding caloric require- ments.

Besides keeping track of the caloric value of the food we eat, it's possible to estimate our metabolic rate fairly closely by measuring our daily fluid intake, and subtracting the amount of urine produced during 24 hours. The missing water was evaporated, and with moderate atmospheric humidity, we evaporate about a liter of water for every 1000 calories we burn.

One of the roles of fat in the food is to stimulate the secretion of bile by the gall bladder. Besides that important function, saturated fats have a variety of protective, antiinflammatory effects, including the reduction of endotoxemia and lipid peroxidation (Nanji, et al., 1997). "Coconut oil completely abolished the responses to endotoxin" (Wan and Grimble, 1987).

Appetizing foods stimulate the digestive secretions, but it's important to avoid foods that directly trigger an inflammatory reaction, or that are indigestible and as a result support harmful bacterial growth. Cellulose can accelerate transit through the intestine and lower estrogen systemically (partly by simply preventing the reabsorption of estrogen that has been secreted by the bile), but the lignans found in many seeds and grains tend to promote inflammation. Raw carrots, for example, lower estrogen, while flax meal can increase it.

Constipation or diarrhea, or their alternation, usually develops when there is inflammation in the bowel. A laxative can sometimes reduce the inflammation, but it's important to identify the

foods that contribute to the problem. A salad of shredded carrot, with oil and vinegar dressing, has a germicidal action, and is stimulating to the digestive processes. Most salad vegetables, though, are likely to produce intestinal irritation, directly or as a result of bacterial decomposition.

One or a few of the antiinflammatory measures can often make a tremendous difference, but for serious chronic problems, it's best to use as many safe techniques as possible, including periodic breathing in a paper bag to increase carbon dioxide retention, and taking niacinamide to inhibit lipolysis, until the signs of inflammation begin to subside. Eventually, the goal should be to become "deficient" in the "essential fatty acids," since experiments have shown that such animals are extremely resistant to endotoxin poisoning (Li, et al., 1990).

Meat physiology, stress, and degenerative processes

The US Department of Agriculture claims that the Pure Food and Drugs Act of 1906 and the Meat Inspection Act of the same year were passed because the food industry demanded them. Ordinary historians believe that Upton Sinclair's 1905 serial publication of his novel about the meat industry, *The Jungle*, caused the public and Theodore Roosevelt to pressure Congress to pass the laws. Sinclair's descriptions of the use of poisonous preservatives and deodorants to disguise the smell of rotten meat angered the public and the president enough to overcome the industry pressure that had kept the US Congress from regulating the commercial food supply long after European governments had begun regulating food production and sales.

Before the government's intervention, it was common practice to soak all kinds of meat in water or chemical solutions to increase their weight. At present, the US Department of Agriculture, through the mass media and funding the training of food technologists and "meat scientists," now takes the position that it is natural for meat to leak water after it is packaged, and says it is perfectly legal for meat producers to soak the meat in water with chemicals until it has increased its weight by 8%. The chemicals, such as trisodium phosphate (in a solution strength as high as 12%), are chosen because they powerfully stimulate swelling and water retention. Considerable amounts of some chemicals, such as sodium citrate, are allowed to add to the weight of the meat. The use of ozone and hydrogen peroxide to deodorize meat causes instantaneous oxidative changes, including lipid peroxidation and protein carbonyl formation, as well as increasing water retention.

Most supermarket meat is now packaged with thick diapers so the buyer won't notice that he is paying for a sizeable amount of pink water. The USDA has an internet site, and consumer hotlines, to inform angry consumers that they are mistaken if they believe that meat shouldn't leak. They explain that meat is now "bred" to contain less fat, and so it contains more water, and that it is simply the leanness of the meat that accounts for its poor flavor.

Before the slaughtered animal is put into the soaking solution to gain a specific amount of weight, the animal has almost always been treated in ways that cause it to go to slaughter in a state of massive edema. Even before the meat is soaked, the animal has been treated to maximize its water retention.

Muscle physiologists and endocrine physiologists know that fatigue, stress and excess estrogen can cause the tissues to swell hugely, increasing their weight and water content without increasing their protein content.

As soon as cheap synthetic estrogens, such as DES, became available in the 1940s, their use in animals was promoted because it was clear that they caused massive water retention. Women who suffer from hyperestrogenism always have a problem with water retention, but they have never been known to suffer from over-developed skeletal muscles. In fact, in humans of both sexes, an excess of estrogen has been commonly associated with sarcopenia, muscular dystrophy, and atrophy of the skeletal muscles. Similar observations have been made in a variety of animals. Meat scientists are the only people I know of who have ever referred to estrogen as an anabolic steroid, in the sense of "building muscle."

When it was publicized around 1970 that DES is powerfully carcinogenic, after it had been used for several decades in the meat industry, its use was outlawed, but its illegal use continued and

was overlooked by the US government. The Swiss government has rejected meat from a large producer in Kansas because it contained DES. Other estrogens are openly used, and the US government continues to apply pressure to other countries to accept meat exports containing estrogens.

There are many ways to increase the water content of meat, besides feeding estrogen to the animal and soaking the meat after slaughter. Everything that causes water retention and tissue swelling in the living animal, that is, every kind of stress, fatigue, poisoning, malnutrition and injury, will make the animal gain weight, without consuming expensive nutritious food. Crowding, fright, and other suffering increase water retention and accelerate the breakdown of fats and proteins.

The water content of meat shouldn't be increased by any of those methods, not only because it is a form of stealing from the consumer, but because it makes the product toxic and unappetizing, and makes the production process a degrading experience.

Any chemicals, such as estrogen or arsenic, that remain in the meat are of course harmful to the consumer, but the changes they produce in the animals' tissues are the main problem. When grains and soybeans are used for fattening animals, their characteristic fatty acids are present in the meat, and are harmful to the consumer, but their complex degradation products, such as isoprene, acrolein, and isoprostanes, remain, along with the complex changes they induce in every aspect of the tissue. The reactive products of oxidative fat degradation stimulate, among other things, the adaptive/defensive production of polyamines, small molecules derived from amino acids. The polyamines, in turn, can be oxidized, producing highly toxic aldehydes, including acrolein (Sakata, et al., 2003). These molecules stimulate cell multiplication, and alter, at least temporarily, the way the cell's genes function.

An excess of water stimulates cell division, and an important mechanism in producing that effect is the increased production of polyamines by the enzyme ornithine decarboxylase. This enzyme is activated by an excess of water (hypotonicity), by estrogen, and by stress.

Besides stimulating cell division and modifying the cell's state of differentiation (including developmental imprinting), the polyamines also contribute to nerve cell excitation and excitotoxicity. Estrogen and excess water can contribute to nerve cell excitation, for example producing convulsive seizures. The polyamines are increased during seizures, and they can affect the stability of the nerve cells, for example contributing to cocaine's seizure-sensitizing action. Although they tend to block free radicals, they accelerate nerve injury (Yatin, et al., 2001), and can contribute to breakdown of the blood-brain barrier (Wengenack, et al., 2000, Koenig, et al., 1989).

The polyamines are increased in cancers, and therapies to block their formation are able to stop the growth of various cancers, including prostate, bowel, and breast cancer. Metabolites of the polyamines in the urine appear to be useful as indicators of cancer and other diseases. (In pancreatic cancer, Yamaguchi, et al., 2004; in cervical cancer, Lee, et al., 2003; in adult respiratory stress syndrome, Heffner, et al., 1995.) The quantity of polyamines in the urine of cancer patients has been reported to be 20 times higher than normal (Jiang, 1990). Polyamines in the red blood cells appear to indicate prognosis in prostate cancer (Cipolla, et al., 1990).

The polyamines in semen have been suspected to have a role in producing cervical cancer (Fernandez, et al., 1995).

In protein catabolism, one fate of the protein's nitrogen is to be converted to the polyamines, rather than to urea. In plants, at least, these small molecules help cells to balance osmotic stresses.

Adding water to meat, or stressing the animals before slaughter, will increase the meat's content of the polyamines, but the longer the meat is stored, the greater will be the production of reactive oxygen products and polyamines.

The deliberate "aging" of meat is something that the meat scientists often write about, but it has a peculiar history, and is practiced mainly in the English speaking cultures. When a supermarket in Mexico City began selling U.S.-style meat for the American colony, I got some T-bone steaks and cooked them for some of my Mexican friends. The meat wasn't water-logged (it was

1962, and the beef had been grown in Mexico), but it had been aged for the American customers, and though my friends ate the steaks for the sake of politeness, I could see that they found it difficult.

In Mexico, even in the present century, butcher shops often don't have refrigeration, and they don't need it because they sell the meat immediately. The fresh meat tastes fresh. Traditionally, liver is sold only on the day of slaughter, because its high enzyme content causes it to degrade much faster than the muscle meats. When it is fresh, it lacks the characteristic bad taste of liver in the US.

Both the liver and the muscles contain a significant amount of glycogen when they are fresh, if the animal was healthy. At first, the lack of oxygen causes the glycogen to be metabolized into lactic acid, and some fatty acids are liberated from their bound form, producing slight changes in the taste of the meat. But when the glycogen has been depleted, the anaerobic metabolism accelerates the breakdown of proteins and amino acids.

In the absence of oxygen, no carbon dioxide is produced, and the result is that the normal disposition of ammonia from amino acids as urea is blocked, and the polyamines are formed instead. The chemical names of two of the main polyamines are suggestive of the flavors that they impart to the aging meat: Cadaverine and putrescine. After two or three weeks of aging, there has been extensive breakdown of proteins and fats, with the production of very complex new mixtures of chemicals.

Mexicans, despite their low average income, have a very high per capita consumption of meat, as do several other Latin American countries. Argentina has a per capita meat consumption of nearly a pound a day. There is a lot of theorizing about the role of meat in causing cancer, for example comparing Japan's low mortality from prostate cancer, and their low meat consumption, with the high prostate cancer mortality in the US, which has a higher meat consumption. But Argentina and Mexico's prostate cancer mortality ranks very favorably with Japan's.

If meat consumption in the US contributes to the very high cancer rate, it clearly isn't the quantity of meat consumed, but rather the quality of the meat.

The polar explorer Vilhjalmur Stefansson was interested in the health effects of a diet based on meat, because of his observation that fresh meat prevented scurvy much more effectively than the fruits and vegetables carried by other polar explorers. He commented on the importance of culture and learning in shaping food preferences:

"In midwinter it occurred to me to philosophize that in our own and foreign lands taste for a mild cheese is somewhat plebeian; it is at least a semi-truth that connoisseurs like their cheeses progressively stronger. The grading applies to meats, as in England where it is common among nobility and gentry to like game and pheasant so high that the average Midwestern American or even Englishman of a lower class, would call them rotten.

"I knew of course that, while it is good form to eat decayed milk products and decayed game, it is very bad form to eat decayed fish. I knew also that the view of our populace that there are likely to be "ptomaines" in decaying fish and in the plebeian meats; but it struck me as an improbable extension of the class-consciousness that ptomaines would avoid the gentleman's food and attack that of a commoner.

"These thoughts led to a summarizing query; If it is almost a mark of social distinction to be able to eat strong cheeses with a straight face and smelly birds with relish, why is it necessarily a low taste to be fond of decaying fish? On that basis of philosophy, though with several qualms, I tried the rotten fish one day, and if memory serves, liked it better than my first taste of Camembert. During the next weeks I became fond of rotten fish."

Since Stefansson's observations nearly a century ago, most Americans have become accustomed to the taste of half-spoiled meat, as part of the process of adapting to an industrial-commercial food system. Tests done by food technologists have found that most Americans prefer the taste of synthetic strawberry flavor in ice cream to the taste of ice cream made with real

strawberries. If it took Stefansson only a few weeks to become fond of rotten fish, it isn't surprising that the public would, over a period of many decades, learn to enjoy a diet of stale foods and imitation foods.

Polyamines are increased in stressed and stored vegetables, as in aged meats. This defensive reaction retards tissue aging, and researchers are testing the application of polyamines to fruits to retard their ripening. A plastic surgeon, Vladimir Filatov, discovered that tissue stored in the cold stimulated the healing process when used for tissue reconstruction, such as corneal transplants. He found that stressed plant tissues developed the same tissue stimulants. Another pioneer of tissue transplantation, L.V. Polezhaev, saw that degenerating tissue produced factors that seem to activate stem cells.

Although the diffusion of these stimulating factors from stressed tissues normally functions to accelerate healing and tissue regeneration, under less optimal conditions they are undoubtedly important factors in tissue degeneration and tumor formation. For example, the bystander effect (contributing to delayed radiation damage, and producing a field of precancerous changes around a cancer), in which substances diffusing from injured tissues damage surrounding cells, involves disturbances in polyamine metabolism.

The direct, optimal effects of the polyamines are protective, but when excessive, prolonged, or without maintained cellular energy, they become harmful.

The expression of genes involves their physical arrangement and accessibility to enzymes and substrates. The negatively charged nucleic acids are associated with positively charge proteins, the histones. The very small positively charged polyamines can powerfully modify the interactions between histones and DNA. In recent years people have begun to speak of the "histone code," as a kind of expansion of the idea of the "genetic code." But the polyamines, produced in response to stress, might be thought of as a complex expansion of the "histone code."

The addition of small molecules, methyl and acetyl groups, to the large molecules can regulate the expression of genes, and these patterns can be passed on transgenerationally, or modified by stress. Barbara McClintock's "controlling factors" were mobile genes that caused the genome to be restructured under the influence of stress. Her discoveries were the same as those made by Trofim Lysenko decades earlier, and like his observations, McClintock's were angrily rejected until the 1980s, when the genetic engineering industry needed some scientific background and natural precedent for their unnatural intervention in the genome.

The brain is extremely different from a malignant tumor, and the derangements produced by stress, by high cortisol and estrogen and an excess of water, are different in the two types of organ (considering the tumor as an *ad hoc* organ), but the polyamines have central roles in the degenerating brain and in the divergent disorganization of tumors. Their importance in stress physiology is coming to be recognized, along with the meaning of "epigenetic development," in which the influence of the environment becomes central, rather than just a place in which the "genotype" is allowed to passively express its "genetic potential." Every developmental decision involves an evaluation of resources and their optimal marshaling for adaptation. The polyamines are part of the cytoplasm's equipment for controlling the genome. The ratio between the different types of polyamine governs the nature of their regulation of cellular functions.

The old idea, "one is what one eats," has evolved far beyond ideas of simple nutritional adequacy or deprivation, and it's now commonly accepted that many things in foods have fairly direct effects on our brain transmitters and hormones, such as serotonin, dopamine, adrenalin, endorphins, prostaglandins, and other chemicals that affect our behavior and physiology.

In 1957 James McConnell discovered that when flatworms were fed other flatworms that had been trained, their performance was improved by 50%, compared with normal flatworms. Later, similar experiments were done with rats and fish, showing that tissue extracts from trained animals modified the behavior of the untrained animals so that it approximated that of the trained animals. Georges Ungar, who did many experiments with

higher animals, demonstrated changes in brain RNA associated with learning, and he and McConnell believed that proteins and peptides were likely to be the type of substance that transmitted the learning.

A dogmatic belief that "memory molecules" would be unable to penetrate the "blood-brain barrier" allowed most biologists to dismiss their work. Ungar's death, and the hostility of most biologists to their work, have caused their ideas to be nearly forgotten for the last 30 years. Negatively charged molecules such as ordinary proteins tend to be repelled by negative charges on the wall of capillaries, but positively charged molecules spontaneously associate with cellular proteins, and easily penetrate the barrier. Highly positively charged molecules tend to concentrate in the brain (Jonkman, et al., 1983), and people are currently attempting to use the principle to deliver antibodies (which are normally excluded from the brain) therapeutically to the brain by combining them with small positively charged molecules (Herve, et al., 2001). This affinity of the brain for positively charged molecules is gradually being recognized as an important factor in the toxicity of ammonia and guanidine derivatives. As mentioned earlier, even endogenous polyamines can be involved in disruption of the blood-brain barrier.

So, apart from the question of exactly what molecules were responsible for the learning transfer produced by McConnell and Ungar, there should be no doubt that polyamines derived from food can enter tissues, especially the brain. People who eat meat from stressed animals are substantially replicating the experiments of McConnell and Ungar, except that people normally eat a variety of foods, and each type of food will have had slightly different experiences in its last days of life. But the deliberate aging of meat is subjecting it to a standardized stress--two or three weeks of cold storage. Because of the great generality of genetic processes, it wouldn't be surprising if cold storage of vegetables turned out to produce polyamine patterns similar to those of cold storage meats. Air pollution and other stressful growing conditions cause vegetables to have very high levels of polyamines.

Prolonged exposure to certain patterns of polyamines might produce particular syndromes, but the mere fact of increasing the total quantity of polyamines in our diet is likely to increase the incidence of stress-related diseases. Experiments with cells in culture show that added polyamines can produce a variety of extremely harmful changes, but so far, there has been almost no investigation of their specific regulatory functions, of their "code."

Besides rejecting stale foods produced under stressful conditions, there are probably some specific ways that we can protect ourselves from polyamine poisoning.

When the organism is functioning efficiently, its respiration is producing an abundance of carbon dioxide, which protectively modifies many systems and structures. Adequate carbon dioxide protects against fatigue, cellular and vascular leakiness, edema and swelling.

Increasing carbon dioxide will tend to direct ammonia into urea synthesis, and away from the formation of polyamines. Bicarbonate protects against many of the toxic effects of ammonia, and since carbon dioxide spontaneously reacts with amino groups, it probably helps to inactivate exogenous polyamines. This could account for some of the protective effects of carbon dioxide (or high altitude), for example its anti-seizure, anticancer, and antistress effects.

Other things that protect against excessive polyamines are procaine and other local anesthetics (Yuspa, et al., 1980), magnesium, niacin, vitamin A, aspirin, and, in some circumstances, caffeine. Since endotoxin stimulates the formation of polyamines, a diet that doesn't irritate the intestine is important. Tryptophan and methionine contribute to the formation of polyamines, so gelatin, which lacks those amino acids and is soothing to the intestine, should be a regular part of the diet.

Because the polyamines intensity the neurotoxic and carcinogenic effects of estrogen and of polyunsaturated fats, those three types of substance should be considered as a functional unit in making food choices. (Grass-fed organic beef fresh from a local farm would be a reasonable choice.) Unfortunately, the meat industry has

maximized all of those dangers, just for the increased weight of their product.

The idea that putrefaction of the stools causes disease, i.e., intestinal autointoxication, originated with physicians in ancient Egypt. They believed that a putrefactive principle associated with feces was absorbed in to the general circulation, where it acted to produce fever and pus. This description of the materia peccans represented the earliest forerunner of our present notion of endotoxin and its effect. The ancient Greeks extended the concept of putrefaction to involve not only the residues of food, but also those of bile, phlegm, and blood, incorporating it into their humoral theory of disease. During the 19th century, the early biochemical and bacteriologic studies lent credence to the idea of ptomaine poisoning--that **degradation of protein in the colon by anerobic bacteria generated toxic amines. Among the leading proponents of autointoxication was Metchnikoff, who hypothesized that intestinal toxins shortened lifespan.** The toxic process, however, was reversed by the consumption of lactic acid-producing bacteria that changed the colonic microflora and prevented proteolysis. The next logical step in treatment followed in the early 20th century when surgeons, chief among them Sir W. Arbuthnot Lane, performed colectomy to cure intestinal autointoxication. By the 1920s, the medical doctrine fell into disrepute as scientific advanced failed to give support. However, the idea persists in the public mind, probably as an extension of the childhood habit of toilet training.

"l-Arginine is metabolized either to polyamines through arginase and ornithine decarboxylase (ODC) activities or to citrulline and nitric oxide (NO, nitrogen monoxide) through the NO synthase (NOS) pathway. Polyamine levels and ODC activity are high in tumor cells. The aim of this study was to test whether N(G)-nitro-l-arginine methyl ester (l-NAME), an inhibitor of NOS, modulates colon carcinogenesis." "In l-NAME-treated rats, the number of ACF was higher than in controls by 47%. ODC activity was enhanced by 11-fold. S-Adenosyl-methionine-decarboxylase activity and putrescine concentration were significantly increased in the colonic mucosa of l-NAME-treated rats. The data suggest that l-NAME promotes carcinogen-induced preneoplastic changes in the colon by inhibiting NOS activity and by stimulating polyamine biosynthesis."

How do you know? Students, patients, and discovery

"For the real world has inexhaustible splendour, the real life is full of meaning and abundance, where we grasp it, it is full of miracles and glory." *N. Hartmann*

"I am myself plus my circumstances" *Jose Ortega y Gasset*

Knowledge should be useful and provisional.

I think comparing the doctor-patient relationship with the teacher-student relationship can be useful, and it might suggest ways that both of them could be made more productive, with implications for the nature of learning and knowing.

40 or 50 years ago, advocates of student-centered education were encouraged by the popularity of psychologist Carl Rogers' client centered therapy. Rogers was interested in what made some therapists successful, and he found that their personality and attitude, not their theories or techniques, accounted for their success. Successful therapists had three essential traits. They offered their clients acceptance or "unconditional positive regard" and empathic understanding, and they themselves were congruent, not presenting a facade of authority or esoteric knowledge. According to Rogers, "accurate diagnosis" and "specific treatment" didn't have anything to do with helping the client.

Some therapists thought Rogers' approach was impractical, others were sure it was foolish. Medically oriented psychiatrists saw Roger's prestige among psychologists as evidence that psychology wasn't suited for dealing with the "mentally ill," who needed authoritative diagnosis and treatment--such as drugs, convulsive shock, or surgery. Scientifically, however, Rogers' ideas were supported by evidence, and medical psychiatry had no evidence to support many of its diagnostic concepts or their therapeutic usefulness.

Most university professors felt that Rogers' ideas were irrelevant to their educational work, and some clearly saw their own function as being a sort of Malthusian selection of the fittest, and deliberately designed their classes as barriers that only a few could surmount.

When I taught English composition, instructors were told that they must grade according to a standard scoring system for errors of grammar, punctuation, spelling, and diction. Our success was seen in terms of the number of freshmen who had dropped out by the end of the year, as evidence that the department had "high standards." Knowing that system, most students chose to write in the style of the first grade "See Spot run" readers, hoping that they could handle the mechanics of writing if they reduced the complexity and content of their essays. It didn't work, and they didn't improve during the weeks when their mistakes were being brought painfully to their attention. Since I hated reading their meaningless efforts, I told them that I was going to grade them on content, rather than punctuation and spelling, and that they should try to write about something that was important to them. Only their success in communicating something would be graded. Their papers became more readable, and the interesting thing was that the mechanical things improved immediately. (The intention to communicate something is the real source of structure in language.) I had another teacher score some of their compositions, and he confirmed that they had improved according to the department's system. The attempt to steer a person can make it hard for them to move, because it inactivates their own guidance system.

A physics professor would notice that writing classes have a lot in common with psychotherapy,

and would dismiss the possibility that such an approach could be used in serious education.

Professors of medicine see themselves as models of the authority that their students will need to apply in dealing with patients, and the physicians trained in the authoritarian style are likely to see their patients as recipients of their medical knowledge, rather than as occasions for listening and learning something new.

Students entering these disciplines must expect to be disciplined. This means that they learn not to ask silly questions about the fundamental assumptions of their profession. Their common sense of meaning, their original guidance system, must be inactivated to keep them from asking questions such as "is that a disease or a theory?" Some patients find that their physician has little patience for their questions, but most patients don't want to ask questions, because they have been taught to respect the authorities.

Our nervous systems are made up of physiology and culture.

That can be a philosophical problem, because our experience is governed by our composition. In people like Heraclitus, physiology was in the foreground, and in people like Plato, culture was in the foreground. (Heraclitus understood that things are always becoming, Plato believed that change wasn't real.) To change someone's mind, it's necessary to change the way they experience themselves and the world, and that requires changing their substance.

In the 1950s a group called "Synectics" was formed to study the creative process. They found that having an expert in the group could be useful, but it could also often stifle the group's ability to find a good solution to a problem. W.J.J. Gordon described their method as "trusting things that are alien, and alienating things that are trusted." They used metaphorical thinking to help them to see the complexity and potentiality of a situation, and to go beyond the existing understanding.

Professors and physicians too often present themselves as having "definitive knowledge" about a subject. For people who already have "definitive knowledge" about something, anomalous facts (if they are perceived at all) will simply remain anomalous and will be quickly forgotten. The things they produce will be extensions of what already exists. For others, things that aren't easily explained have special interest, and cause them to ask new questions. New perspectives can lead to new possibilities and new realities.

Once during a lecture, Alfred Korzybski offered his students some cookies, which they seemed to enjoy, then he showed them a label on the bag, "dog cookies," and some of them felt sick. "I have just demonstrated that people don't just eat food, but also words, and that the taste of the former is often outdone by the taste of the latter." Hypnotists have often demonstrated that words can have physiological effects.

Many of our institutions use language as a system for preserving culture, that is, for preventing change. Korzybski wanted to correct the cultural habit of making abstractions seem like objects or "elements," by making people aware of the degree of abstraction in their words. This can be useful, but his book has been used to promote an extreme linguistic relativism in the theory of knowledge and science, placing "meaning" entirely within the nervous system.

This approach evades the fact that patterns exist objectively, and that they can be perceived as they unfold through time. Although Korzybski thought he was teaching people to overcome the limitations of thinking in the style of Aristotle or Plato, he was supporting an attitude that would make it impossible to perceive in the style of Heraclitus.

If Heraclitus said it's impossible to step in the same river twice, his comment was directed to those who ignore the rich complexity of experience because of stereotyped "elemental" thinking. He was pointing to the abundance of the world, but elemental-concept thinkers have felt that he simply negated their objective meanings.

To perceive another person accurately requires the ability to perceive the person as a pattern unfolding coherently through time, as a potential realizing itself. Carl Rogers' insight was that one's awareness of being perceived in this way encourages the unfolding of potentials.

The refusal of institutions or individuals to perceive others in this way is an imposition of their way of understanding, and is itself a form of oppression. People who think in terms of "professional training" often describe learning in terms of

"conditioned reflexes," producing a desired response to each stimulus.

The terms "conditioned reflex" and "conditioning" were introduced into psychology by the behaviorist J. B. Watson, who mistranslated and misrepresented Pavlov's ideas, and who insisted that the ideas of consciousness, volition, and self should be eliminated from the science of psychology.

The orienting reflex, the alertness provoked by something new, was described by Sechenov in 1863, and explored by Pavlov (who also called it the "what *is* that? reflex" and the "exploration reflex") who considered it to be our most basic and most powerful reflex. The fact that novelty powerfully arouses our exploratory systems means that we have a mental image of our familiar environment, and that a change in that environment requires us to investigate the properties of the new thing, to see whether it can be explained by the things we already know, or whether it requires us to change our basic ideas about our place in our surroundings. For Pavlov, the study of psychology or physiology without consciousness was simply crazy.

Pavlov said that he studied nutrition to understand consciousness and the nervous system, because eating is our closest interaction with the world. Our brain is part of our digestive system. But eating has become highly institutionalized and influenced by our cultural beliefs. If people begin to think about the meanings of eating, they are beginning a process of cultural and philosophical criticism.

Helping people with physical problems (such as obesity, headaches or joint or nerve pain, or named diseases) and helping people who want to understand something about the world beyond themselves, are structurally similar, but in the issues of health the questions and the potential answers are more clearly present and immediate.

The Synectics group began with the study of artistic creation, but they found that it was easier to evaluate their progress when they concentrated on technical invention. They found, as Pavlov had, that consciousness and meaning could best be studied in concrete situations. The process of goal-seeking was to be studied in action.

I see the therapeutic or educational or productive situation as a goal-directed biological and social interaction, and the goal can be either the creation of something new and better, or simply the preservation and application of something already existing.

Until just about a generation ago, "teleology" (especially in biological explanation) was considered to be metaphysical and inappropriate for science. Norbert Wiener, who coined the word "cybernetics" (from Greek for "proficient pilot" or "good steersman") helped to change attitudes toward the word when he used the phrase "teleological mechanism" to describe cybernetic control systems.

A goal-directed system is one that senses its actions and makes adaptations so that its actions can be refined to achieve a purpose. Between 1932 and 1935, a student and colleague of Pavlov's, P.K. Anokhin, developed this idea of self-regulating systems, and originated the concept of feedback, in describing the ways organisms guide themselves and their adaptations. Building on Pavlov's work, and investigating the origins of innate reflexes, he found principles that would explain the origin of organs and their functions, and that would also apply to the interactions between individuals. The functional system on any level, in embryology, psychology, or society, is a sequence of interactions with a useful result. Movement towards a goal is adaptive, and the system is shaped by the adaptations it makes in moving toward the goal. Resources are mobilized to meet needs, changing the system as it moves towards its goal.

Since there is always novelty in the real world as contexts change, the exploratory function is causing us to continually revise our understanding. Every question forms a functional system, and our brain adapts as we find answers.

This kind of systems theory and self-regulation theory developed along with the field theories in embryology, psychology, chemistry, and some branches of physics. Pattern and analogy were central to their approach. The functional systems are processes that occupy time and space.

The "field" idea in biology (wholes shaping themselves) can be understood by considering its

opposite, the belief that cells are guided by their genes (producing a mosaic of parts). That idea, in its extreme form, claimed that cells contained an internal map and an internal clock telling them when and where to move and how to change their form and function as they matured and aged. In reality, cells communicate with surrounding cells and with the material between cells. The existence of long-range ordering processes between atoms, molecules, and cells threatened some of the central dogmas of the sciences.

Although Norbert Wiener popularized some aspects of the "teleological" approach to regulatory systems in the 1950s, and saw analogies between the teleological machines and the way the brain functions in Parkinson's disease, by 1950 the digital approach to information processing, storage, and transmission was displacing analog devices in computation and engineering, and was compatible with theories of intelligence, such as neo-Kantianism, that believed that human intelligence can be defined precisely, in terms of discrete rules and operations. Field thinking in embryology, cancer theory, psychology, and other sciences effectively disappeared--or "was disappeared," for ideological reasons.

Wiener's goal-directed machines, like Anokhin's functional systems, worked in space and time, and the idea of steering or guidance assumes a context of time and space in which the adjustments or adaptations are made. Analog computers and control systems in various ways involved formal parallels with reality. The components of the system, like reality, occupied space and time.

Digital computers, with their different history and functions, for example their use for creating or breaking military codes, didn't intrinsically model reality in any way. Information had to be encoded and processed by systems of definitions. A sequence of binary digits has meaning only in terms of someone's arbitrary definitions.

Parallel with the development of electronic digital computing machines, binary digital theories of brain function were being developed, by people who subscribed to views of knowledge very different from those of Anokhin and Wiener. (Anokhin argued against the idea that nerves use a simple binary code.) These computer models of intelligence justify educational practices based on authoritative knowledge and conditioned (arbitrary) reflexes. Neo-Kantianism has been the dominant academic philosophy in the U.S., turning philosophy into epistemology to exclude ontology. "Operationism" and logical positivism share with neo-Kantianism its elimination of ontology (concern with being itself).

In the 1960s, Ludwig von Bertalanffy developed a theory of systems, defining a system as an "arrayed multitude of inter-linked elements." Although it was intended as a description of biological systems, it reduced the teleological factors, needs and goals, to a kind of mechanical inner program, such as "regulatory genes." "Following old modes of thought, some called this orderliness of life 'purposiveness' and sought for the 'purpose' of an organ or function. However, in the concept of a 'purpose' a desiring or intending of the goal always appeared to be involved--the type of idea to which the natural scientist is justly unsympathetic" (von Bertalanffy).

His system theory was highly compatible with programmed digital computers, that could define the interactions of "elements," but unlike Anokhin's definition of functional systems, it lacked a pattern-forming mechanism. In Anokhin's view, the system is formed by seeking its goal, and perceiving its progress toward the goal.

Carl Rogers' approach to person-centered processes recognized that the interacting therapist and client or teacher and student were a formative system, rather than just an occasion for one to inform the other.

In the Synectics group, they learned to identify the types of deeply involved interaction that would lead to the best inventions. As in Anokhin's functional systems, resources are mobilized or generated as they are needed. Like Anokhin, they showed that the process of creating something new can be understood and controlled.

Every meaningful interaction involves formative systems.

Stimulation of sensory nerves can cause cells to move into the stimulated area, causing the organ to grow. Environmental enrichment causes brains to become larger, and to metabolize at a

higher rate. All of these processes, from the level of energy production to the birth of new cells and the creation of new patterns in the brain, are called up in the formation of a functional system.

The studies of organismic coherence by Mae-Wan Ho and Fritz Popp appear to support the idea that even the alignment of molecules in cells is responsive to the state of the entire organism.

The reason this seems implausible to most biologists is that cells are commonly still seen as analogous to little test-tubes in which chemical processes occur as the result of random collisions between molecules floating in water. But Sidney Bernhard's study of glycolysis showed that the reactive sugar molecules are passed individually from one enzyme to the next, in an orderly manner.

In this system, the flow of energy, a series of oxidations and reductions changing glucose into other substances, effectively "pulls" the molecules through the system, contributing to order on a molecular level. Function creates structure, which supports function.

Self-regulating systems are self-ordering systems. When a person is allowed to function freely as a goal-directed, questioning system, the formation of patterns in the brain will be spontaneous and appropriate, and orderly. Knowing is the ability to hold patterns in awareness. Knowledge, rather than being stored like money in the bank, is something that is regenerated, or generated, as we need it.

When our own steering system is commandeered by the authorities, our patterns of knowledge will be compartmented, and arranged in a fixed pattern. This kind of knowledge either deteriorates, or it seeks more of its own kind.

While self-regulation and the generation of knowledge are pleasurable, having knowledge imposed isn't.

Korzybski was right in warning about the dangers of letting names become "elements." This perception led Paolo Freire to emphasize the educational importance of critically giving things their appropriate names, rather than just "banking" the names given by an authority. "To exist, humanly, is to name the world, to change it. **Once named, the world in its turn reappears to the namers as a problem and requires of them a new naming.** Human beings are not built in silence, but in word, in work, in action-reflection." ". . . to speak a true word is to transform the world." "'Problem-posing' education, responding to the essence of consciousness--intentionality--rejects communiques and embodies communication" (Freire, 1993).

Having the power to assign names is a source of power and wealth. The pharmaceutical industry has been accused of inventing new diseases to sell new drugs for treating them. Old definitions of cancer are hard to change, when the medical profession has invested so much in treatments--radiation and cytotoxic chemotherapy--which conflict with newer biological understanding of cancer.

The person who is learning is critically interacting with both nature and culture, with practical issues and theories.

Applying this to practical problems of health and nutrition, a first step is to begin to think about which things are theories or deductions from theories, which are habits, and which things are felt needs or appetites, and to get in the habit of watching processes or things--such as "signs" and "symptoms"--develop through time.

With practice, people can begin to see themselves as functional systems in their main activities, such as eating, and to watch how their needs influence their actions, and what effects different ways of eating have on their other functions, such as sleeping and working. Do appetites govern the timing of meals and the choice of foods? How does the time of day or time of month affect appetites? People often watch for effects of foods, but usually only for a few minutes or hours after eating. Some foods can produce symptoms days after they were eaten, and the activation of the digestive system by a recent meal can cause a reaction to something eaten previously.

Our traditional cultures, and advertising and schools give us definitions and expectations relating to foods and symptoms and physiology, and they teach us to think of our bodies in terms of an "immune system," "endocrine system," "digestive system," "nervous system," and "circulatory system," which are mainly anatomical concepts that are more useful to the drug companies than to

the consumer of culture. Both conventional and alternative approaches to medicine and health are likely to let those arbitrary ideas of systems cause them to overlook real, but unnamed, processes.

When the organism is seen as a mosaic of parts, rather than as a system of developing fields, medical treatments for one part, such as the "circulatory system," are likely to cause problems in other "systems," because the "parts" being treated don't exist as such in the real organism, with the result that the treatments are seldom biologically reasonable.

Besides learning to perceive one's own physiology and becoming aware of the processes of perceiving and knowing so that they can be improved, it's important to seek information to expand the interpretive framework, and to look for new contexts and implications.

Reading with a critical imagination is as important for science as it is for literature or advertising. Good literature often opens expansive new ways of seeing the world, and good science writing can do that too, but too often scientific publications have ulterior motives, and should be read the way advertising propaganda is read.

Some publications now require authors to state their conflicts of interest (such as receiving money from a drug company while testing a drug), but editors and publishers, who choose which studies will be published, seldom reveal their conflicts of interest. As Marcia Angell showed, editorial choices can turn statistical randomness into statistical significance. Private ownership of scientific journals permits control of their content.

Besides being aware of the conflicts of interest and the frequent insignificance of "statistical significance," it's possible to recognize some features of the style of argument which is often used in science propaganda. A deductive style, rather than a descriptive and inductive style is extremely common in technical writing, and it should always lead the reader to question the principle from which deductions are made.

"Membranes are made from Essential Fatty Acids, therefore those fatty acids are nutritionally essential." But cells can multiply in a culture medium that provides no fats. In biology, the most popular "principles" are simply dogmatic beliefs about genes and membranes.

In physics, where testable inferences can be drawn from arbitrary assumptions or doctrines, predictions that may be made based on different assumptions are often ignored for ideological reasons. This ideological quality of physics can permeate the other sciences when they use reductionist explanations.

Korzybski felt he was helping humanity to escape "word magic" and to advance to a mathematical view of the world. But the same processes that caused people to "confuse words with things" can cause people to confuse mathematical descriptions with reality.

"Chaos theory," which was a faddish excitement about the ability to generate unpredictable output from a simple rule (which could be endlessly repeated by a computer), has been suggested to explain many things in biology, including heart rate variability. It doesn't. Instead, it has probably had a slightly harmful effect, by distracting attention from real biological pattern-forming processes.

Real substance can sometimes be modeled by descriptions of randomness, but substances at all levels have intrinsic pattern-forming tendencies, and context-dependent histories. Water, for example, has structure and structural memory that can affect even simple chemical reactions, and even gases have internal complexities that are often ignored. Real observations shouldn't be distorted by theories. The ideal atomic of the reductionists are a crude fantasy, invented, more or less consciously, to serve their ideological purposes. One purpose is to support their abstract models of reality. A particularly nexious way of modeling reality has been based on the assumption of randomness, justifying a statistical view of all things.

The neo-Kantian philosophy that has dominated US universities for more than a century argues that our senses (even when extended instrumentally) are limited, so our knowledge must be limited--we can only speak of theories or interpretations, not of being. The world we see is, according to them, only an artifact of our senses. A popular example is that the flower a bee sees is different from the flower a human sees, because the bee's eye is sensitive to ultraviolet light. (The triviality of the example is shown by the fact that

when a person's lens is removed because of a cataract, ultraviolet light becomes visible, because it is no longer blocked by the tissue that is many times thicker than a bee's lens.) There is a straw-man quality to their arguments against philosophical realism and empirical science: No one claims that our senses deliver complete knowledge all at once. What the realists claim is that interacting with the world is an endless source of valid knowledge.

When reading science articles, or listening to lectures, and even while privately thinking about experiences, it can be useful to watch for the improper use of assumptions. Our understanding has been shaped by the assumptions of our culture, and these assumptions present an attitude toward the nature of the world, in some cases even about the ontology that our philosophers have said is beyond our reach. "Evolution is shaped by random mutations," "nuclear decay is random," "the universe is expanding," "entropy only increases," "DNA controls inheritance," "membrane pumps keep cells alive," and all of the negative assumptions that have for so long denied the systematic generation of order.

Every communicative interaction is an opportunity for the discovery of new meanings and potentials.

Aristotelian motto: If the knower and the known form a functional system they are substantially the same.

Fatigue, Aging, and Recuperation

Old people and sick people tire easily. Surprisingly, little is known to explain that common fact.

Myths about lactic acid and oxygen debt have misdirected most fatigue research.

The cellular processes involved in fatigue overlap with those of aging.

Knowledge about the mechanisms of fatigue should be useful in preventing some tissue swelling disorders, organ failure, degenerative calcification, and other energy-related problems.

Unlike the somewhat technical medical concept of "stress," the idea of fatigue is something everyone understands, to some extent. Hans Selye's studies of stress weren't widely accepted until about 40 years after their publication, but some of the main investigators of the fatigue phenomenon are still practically unknown in the universities, many years after they published their work.

Several things have kept fatigue research from advancing, including the common feeling that fatigue is already sufficiently understood, and that it is somehow trivial, compared to problems such as growth, reproduction, and disease.

Fatigue is usually described as decreased responsiveness resulting from over-exertion: For example, a muscle's decreased strength or speed of contraction, or a nerve's decreased speed of conduction, or a sense organ's decreased ability to detect or to discriminate. Another meaning of fatigue, a decreased resistance or strength, can be applied to materials, as well as to some biological functions, for example when fatigue leads to sickness or infections.

"Responsiveness" implies sensitivity, and decreased sensitivity to stimulation can be seen in fatigued sense organs, nerves, muscles, and many other types of cell--immune cells, secretory cells, etc. Even plant cells have very similar processes of excitability that can be depleted by repetition.

In a series of lectures to the Royal Society in England (1895-1901), the physicist Jagadis Chandra Bose described work that at first excited, and then disturbed, many physicists and biologists. He had invented devices for both producing and detecting electromagnetic waves, and he had been the first to produce millimeter length radio waves (microwaves). In Marconi's first transatlantic radio transmission Bose's signal

GLOSSARY:

Uncoupling --In cellular respiration, oxidation of "fuel" in the mitochondrion is coupled to the phosphorylation of ADP, forming ATP. Uncouplers are chemicals that allow oxidation to proceed without producing the usual amount of ATP.

DNP--Dinitrophenol --an uncoupler that was once popular as a weight-loss drug.

NAD+ and NADH --*Nicotinamide adenine dinucleotide, and its reduced form are coenzymes for many oxidation and reduction reactions in cells.*

Hyperammonemia --The presence of too much ammonia in the blood.

Vicinal water --water near surfaces, especially hydrophobic surfaces, that is physically and chemically different from ordinary water.

Hydrophobic --insoluble in water, a non-polar oil-like molecule that repels water.

detecting device was used. This device was based on the fact that two pieces of metal in superficial contact became electrically fused (cohered) in the presence of an electrical or electromagnetic field. After they cohered, a mechanical shock would separate them, breaking the electrical fusion.

When Bose was experimenting with his "self-restoring coherer," a semiconducting device that spontaneously broke the connection without being mechanically shaken, he observed that it became insensitive after prolonged use, that is, it lost its self-restoring capacity, but that after a rest, it recovered its sensitivity. He recognized the complex behavior of his instrument as being very similar to the electrical physiology of living cells.

He then began a series of experiments on plants, animals, and minerals, that showed similar responses to all kinds of stimulation, including mechanical and thermal and electromagnetic.

The idea of metal fatigue wasn't new, but Bose was able to think far beyond the ideas of the metallurgists. Biologists were thinking of electrical responsiveness as a defining feature of life, and Bose demonstrated that plants had electrical responsiveness very similar to that of animals, but also that similar reactions could be demonstrated in minerals.

This was what disturbed the English scientists. Sensitivity, irritability, fatigue, and memory were supposed to be special properties related to life, and maybe to consciousness. For the Englishmen, there were religious implications in this Hindu's research.

There were several reasons that European and American scientists couln't accept the universal nature of the electrical properties that they were studying in animals. One of their motives was to see life as something immaterial, or of an absolutely different nature than inorganic matter. Another problem had to do with the developing belief that the special properties of life were enclosed in the hereditary substance of each cell, and that the electrical functions of cells were produced entirely by the presence of a membrane, surrounding a drop of water containing randomly moving dissolved chemicals. For the membrane electricity theory, it was essential to believe in the random behavior of things dissolved in the cell water.

So they considered the electrical-mechanical reactions and interactions of minerals to be so unlike the processes of life that it was inappropriate to see analogies between them. Minerals were composed of atoms, and, according to the doctrine of the time, they could have no integral "physiological" functions except on the atomic scale. It was more than 20 years before mainstream physicists began thinking about "delocalized" forces and fields in minerals.

Between 1915 and 1934, Michael Polanyi made many observations that made it clear that the old kind of electrical atomism was completely unfounded. The behavior of mineral crystals, and the interactions between different phases of material, such as gas or liquid with a solid, could be understood only in terms of relatively long-range forces. Polanyi's experiments showed, for example, that events on the surface of a crystal modified the strength and deformability of the crystal.

Many others between 1900 and 1940--Lepeschkin, Nasonov, Bungenberg de Jong, and Solco Tromp, for example--argued that the sensitivity of protoplasm had to be understood in terms of long range order, something like a liquid crystalline state of matter that would require some of the kinds of knowledge of matter that were being developed by physicists, metallurgists, and a variety of others investigating the condensed states of matter.

But the mainstream biologists preferred to describe cells in terms that would make impossible any of the responsivities or sensitivities seen in the "simple" solid state of minerals. To defend their ideology of the immateriality of life, they denied that the subtlest features of matter had anything to do with life, reducing life to a debased set of special, merely theoretical, mechanisms. The now defunct physical theory of merely localized atomic electrical forces became the paradigm for the new biology. The many demonstrations of coherent, ordered physical behavior of the cytoplasm, for example Gurwitch's mitogenic radiation, were dismissed with prejudice.

During G. W. Crile's long career (1889-1941), understanding shock, biological energy, and fatigue were his main concerns. He believed that shock was the result of brain exhaustion, and in one of his last publications he showed that the brains from exhausted animals produced less bioluminescence than those from rested animals. His importance was in demonstrating that fatigue and shock are systemic conditions of the organism, rather than isolated events in muscles and nerves. Recent publications are showing the validity of this view. Crile's approach to the prevention and treatment of shock was based on isolating the damaged area with local anesthetics. Blocking the nerves from one injured part of the body, for example the sciatic nerve in the leg, could preserve energy production (and normal cell functions) throughout the rest of the body.

About 30 years earlier (1901), Vvedensky had demonstrated that some types of fatigue appear to be a defensive blocking of responsiveness, such that intense stimulation would produce no response, while weak stimulation could sometimes produce a response. These changes affected cell functions in a variety of ways, that he called narcosis and parabiosis.

There have been two popular ways to "explain" fatigue, one by saying that the cell's energy (usually thought of as ATP or glycogen) is used up, the other saying that the accumulation of a metabolic product (usually lactic acid) prevents further functioning. The obvious problem with these explanations is that the fatigue response is quite independent of those metabolic changes. Another problem is that those ideas don't explain the real changes that occur in cells that are demonstrating fatigue.

Fatigued cells take up water, and become heavier. They also become more permeable, and leak. When more oxygen is made available, they are less resistant to fatigue, and when the organism is made slightly hypoxic, as at high altitude, muscles have more endurance, and are stronger, and nerves conduct more quickly. These facts don't fit with the standard model of the cell, in which its sensitivity is strictly governed by the behavior of its "membrane." (For example, how can a membrane leak large molecules at the same time that it is intact and causing the cell to swell osmotically?) They are consistent with the model of the cell that treats protoplasm as a special phase of matter.

Another feature of fatigue (and often of aging, stress, and sickness) is that the relaxation of muscles is retarded and impaired.

Hypothyroidism causes muscle relaxation to be slowed, both in skeletal muscles and in the heart. F/Z. Meerson showed that stress causes heart muscles to be exposed to increased calcium, followed by breakdown of fats and proteins, and that these changes keep the injured heart in a continuous state of partial contraction, making it stiff, and resistant to complete contractile shortening. When many cardiologists talk about the heart's stiffness, they are thinking of muscular thickening and fibrosis, but those are late consequences of the kind of contractile, unrelaxed stiffness that Meerson described.

The hypothyroid heart does eventually become fibrotic, but before that, it is just unable to relax properly, and unable to contract fully. This failure to empty fully with each contraction is a kind of "heart failure," but it can be corrected very quickly by supplementing thyroid. Even the fibrotic heart can recover under the influence of adequate thyroid.

The analogy of the "coherer" would suggest that the overstimulated muscle isn't able to decohere itself, until it has had a rest. It responds to stimulation, lets the energy flow, but then can't turn it off, and the energy keeps flowing, because of a change in physical state.

Albert Szent-Gyorgyi was probably the first person to seriously investigate the semiconducting properties of living material. Since he was aware of W.F. Koch's idea of a free radical catalyst to support oxidative metabolism, his suggestion in 1941 that cellular proteins could function as electrical conductors (or semiconductors) was very likely based on his research in cellular respiration, as well as on his work with muscle proteins. He had observed that ATP lowers the viscosity of a solution of the muscle protein myosin, and that it would cause a filament formed by precipitating myosin to contract. The polymerization and contraction of proteins under the

influence of free radicals was at the heart of F.W. Koch's therapeutic ideas, but Koch's work was about 100 years too early, by medical standards.

Szent-Gyorgyi observed that, although ATP was involved in the contraction of muscles, its post-mortem disappearance caused the contraction and hardening of muscles known as rigor mortis. When he put hardened dead muscles into a solution of ATP, they relaxed and softened. The relaxed state is a state with adequate energy reserves.

After Szent-Gyorgyi moved to the U.S., in 1947, he demonstrated the effect of muscle cytoplasm on the behavior of fluorescent substances, which was analogous to that of ice, until the muscle was stimulated. During contraction, the fluorescent material behaved as it would in ordinary liquid water. This effect involved the stabilization of the excited state of electrons. This single demonstration should have caused biologists to abandon the membrane theory of cellular excitation, and to return to basic physics for their understanding of cell behavior. The implications of Szent-Gyorgyi's work were enormous for biology and medicine, and even for the understanding of semiconductors, but most of the world was hypnotized by a simple textbook model of cell membranes.

Szent-Gyorgyi also demonstrated that the combination of properly balanced electron donors and electron acceptors (D-A pairs) would cause a muscle to contract. He compared this to "doping" an inorganic superconductor, to regulate its electronic behavior. Although these experiments were done half a century after Koch's application of free radical chemistry to medicine, they still didn't rouse the pharmaceutical industry from its toxic slumber.

I suspect that it was Szent-Gyorgyi's research with those interesting electronic properties of cellular water and proteins that in 1960 gave Linus Pauling the idea to explain anesthesia, specifically noble gas anesthesia, in terms of water clathrate formation, the restructuring of cellular water by the hydrophobic atom or molecule of an anesthetic. His suggestion caused a reaction among biologists that discouraged research into the subject for about 40 years.

Gilbert Ling's view of cytoplasmic structure gives a different emphasis to the function of electrons, which I think is an essential complement to Szent-Gyorgyi's view. Ling's emphasis is on how the inductive effect of adsorbed substances (for example, ATP and progesterone have powerful adsorptive effects) on proteins changes the charge concentration on ionizable groups. When the charge concentration is in one configuration (more acidic), the preferred counter-ion is potassium, and in another (less acidic) configuration, it is sodium.

Gilbert Ling's biophysical calculations were useful to physical chemists, and were soon put to practical use for understanding ion exchange resins, such as water softeners. Many sorts of evidence showed their validity for cell physiology, but nearly all biologists rejected them, preferring to talk about membranes, pumps, and channels, despite the evidence showing that the properties ascribed to those are simply impossible. NMR imaging (MRI) was developed by Raymond Damadian specifically as an application of Ling's description of cell physiology.

Although metals are conductors, the function of the coherers of Bose and others shows that the surface is a semiconductor, that requires the slight excitation of an electromagnetic wave to become conductive, at which point the conduction band of electrons in the metal becomes coherent and extends from one particle into the others. The surface of any phase of a substance has electronic properties distinct from those of the bulk phase, and in a sense the interface constitutes a special phase of matter. When the electrons of the interface lose their special properties, the structure of the whole system changes.

When a muscle cell is stimulated enough to cause a contraction, the interruption of its resting phase causes a shift in the charge concentration on the proteins, potassium ions are exchanged for sodium ions, calcium ions enter, and phosphate ions separate from ATP, and are replaced by the transfer of phosphate to ADP from creatine phosphate.

Since the quantum physicist E. Schroedinger wrote his book, *Time's Arrow,* people have often thought of life in terms of negentropy, going

against the general tendency of entropy to increase, except for aging and death, which are seen as obeying a law of increasing entropy. But A. Zotin investigated organisms, rather than abstractions about electrons, and shows that aging involves a ***decrease*** in entropy, and a slowing of metabolism. The decrease of entropy with aging, according to his view, would be analogous to crystallization, a sort of progressive freezing.

When a nerve is stimulated, it releases energy suddenly, and much of this heat seems to be the result of a change of structure in the cytoplasm, since (in crustaceans' nerves, which can function at low temperature) during the resting recovery of the nerve, its temperature goes slightly below the ambient temperature, despite the release of some heat from the chemical changes of metabolism, stimulated by the nerve's activity.

When a physical change is endothermic, as the nerve's recovery is, that can be interpreted as an increase in overall entropy, as when a rubber band spontaneously contracts, and becomes cooler.

Bose's rested coherer, which, with time, spontaneously recovered its semiconductive (i.e., relatively insulating) property, wasn't being powered by metabolism. As the particles returned to their relatively isolated state, there was a decrease of order, and the change was probably somewhat like the spontaneous energy change in the stimulated crustacean nerve.

Seeing the structure of the cytoplasm as something like a spring-driven mechanism, able to bounce between two states or "phases," makes it easier to see cellular fatigue as something different from the various metabolic energy sources, ATP, glycogen, and oxygen, which--contrary to conventional assumptions--aren't closely tied to the functional losses occurring in fatigue.

The role of metabolism, then, becomes analogous to the role of the "tapper" in the early forms of the coherer.

Water in its normal state is a dielectric. But when it is polarized by an electrical charge, or by the presence of a phase boundary, its normal state is altered. This is the special **interfacial** water, or **vicinal** water. With the movement of ions (mainly potassium, sodium, calcium, and magnesium) during excitation, the state of the cellular water is necessarily changed by the presence of different substances. In the excited state, cell water is less hydrophobic, more hydrophilic than in the relaxed state. A network of "hydrophobic" interactions extends through the relaxed cell. One of the properties of a dielectric is that it tends to move into the space between charges, with a force similar in principle to that involved in dielectrophoresis.

In the resting state, potassium is the main inorganic ion, and it is associated with acidic groups, such as aspartic and glutamic acid. During excitation, potassium is partly exchanged for sodium, which becomes the preferred counter-ion for the acid groups, and calcium enters the cell along with the sodium. Potassium's interaction with water is very weak (its hydration has been called negative), allowing water to form the structures that are stable in the presence of hydrophobic surfaces. Sodium and especially calcium (smaller atoms, with higher surface charge concentration) powerfully interact with water molecules, more strongly than water interacts with itself, disrupting the delicate somewhat hydrophobic structures of the intracellular water.

(Calcium, with its two charges, has important binding and stabilizing functions in the resting cell. In the excited cell, these internal calcium ions are released, while extracellular calcium ions enter the cell.)

With the increased movement of charged particles during the stimulation of a nerve or muscle, as one kind of counterion is exchanged for another, and the destruction of some of the water's structure, there are more opportunities for bulk dielectric water to enter cells, interfering with the arrangement of proteins, and tending to cause swelling and separation of the structural elements of the cell. Electron micrographs of fatigued muscle show a remarkable separation of the actin and myosin proteins.

In the excited state, NMR studies show that cell water behaves more like bulk water, that is, its molecular movements are relatively free, indicating the momentary loss of the interfacial state. In this state, the uptake of water, and the fatigue-related swelling of nerves and muscles, would be driven at least partly by the principle

that a dielectric tends to be pulled into the spaces separating charges. The bulk water that enters a cell during the breakdown of vicinal water functions as an extraneous material somewhat beyond the cell's control.

These bulk-like high dielectric properties of water in the excited cellular state can explain many changes of enzyme activity. Previously nonpolar lipids would develop a negative surface charge (from accumulating hydroxyl groups: Marinova, et al., 1996), which would tend to increase their oxidation and degradation. With the loss of the interfacial water, the cell's high energy resting state is replaced by an active mobilization of its resources, to maintain and restore the cell's structure. Metabolic energy begins to flow into the processes of restoration, serving the function of the tapper in the earliest coherers.

Looking at fatigability, muscle contraction, and nerve conduction in a variety of situations, we can test some of the traditional explanations, and see how well the newer "bioelectronic" explanation fits the facts. Osmotic pressure, hydrostatic pressure, atmospheric pressure, and the degree of metabolic stimulation by thyroid hormone affect fatigue in ways that aren't consistent with the membrane-electrical doctrine.

The production of lactic acid during intense muscle activity led some people to suggest that fatigue occurred when the muscle wasn't getting enough oxygen, but experiments show that fatigue sets in while adequate oxygen is being delivered to the muscle. Underwater divers sometimes get an excess of oxygen, and that often causes muscle fatigue and soreness. At high altitudes, where there is relatively little oxygen, strength and endurance can increase.

An excess of oxygen can slow nerve conduction, while hypoxia can accelerate it. (Increasing the delivery of oxygen at higher pressure doesn't increase the cellular use of oxygen or decrease lactic acid production in the exercising muscle [Kohzuki, et al., 2000], but it will increase lipid peroxidation.)

High hydrostatic pressure causes muscles to contract, though for many years the membrane-doctrinaires couldn't accept that. Underwater divers experience brain excitation under very high pressure. Since vicinal water has a larger volume than ordinary water (analogous to the expansion when ice is formed, though the volume increase in cell water is slightly less, about 4%, than in ice, which is 11% more voluminous than liquid water), compression under high pressure converts vicinal cell water to the state that occurs in the excited cell, the way ice melts under pressure. The excited state exists as long as water remains in that state.

These changes of state under pressure are reminiscent of Bose's use of pressure in some of his coherers, and of the fact that pressure alters the sensitivity of electrons in a semiconductor, by altering their "band gap," the amount of energy needed to make them enter the conductive zone.

One of the early demonstrations that cell water undergoes a phase change during muscle contraction involved simply measuring the volume of an isolated muscle. With stimulation and contraction, the volume of the muscle decreases slightly. (The muscle was immersed in water in a sealed chamber, and the volume decrease in the whole chamber was measured.) This corresponds to the conversion of vicinal water to bulk-like (dielectric) water. (The threatening implications of those experiments with spontaneous volume change were very annoying to many biologists of my professors' generation.)

In the stimulated state, the cell's uptake of water from its environment coincides closely with its electrical and thermal activity, and its expulsion of water coincides with its recovery. In a small nerve fiber, or near the surface of a larger fiber, these changes are very fast, and in a large muscle the uptake of water is faster than the flow of water from capillaries can match, but it will become massive if stimulation is continued for several minutes. For example, two minutes of stimulation can cause a muscle's overall weight to increase by 6%, but its extracellular compartment loses 4%, so the muscle cells gain much more than 6% of their weight in that short time (Ward, et al., 1996). The water that is taken up by cells is taken from the blood, which becomes relatively dehydrated and thicker in the process.

The belief in "semipermeable membranes" (which hasn't been a viable explanation of cell

physiology for a very long time) forces people to explain cell swelling osmotically, which means that they simply assume that the number of solute particles inside the cell has drastically increased in a very short time. In Tasaki's experiments (1980, 1981, 1982), the swelling in a nerve coincides with the electrical action potential, which, according to the osmotic explanation, means that a very large increase in internal osmolarity happened in essentially no time. The action potential comes and goes in about 2 milliseconds. The swelling also coincides with heat production and shortening of the nerve fiber. The shrinkage of the nerve fiber after the end of the action potential may be just as rapid, and the membrane theory offers no explanation for that, either. (But the restoration of the unswollen state can be very prolonged, depending on conditions extrinsic to the particular muscle or cell.) Troshin's survey of the theory of osmotic regulation of cell volume showed that the idea of the cell as a membrane osmometer was false, but very few biologists read his book.

Since the excited or fatigued muscle or nerve swells and gains weight, it's interesting to see what happens to their sensitivity and strength when they are exposed to hypotonic solutions that tend to promote swelling, or to hypertonic solutions, that help to prevent swelling.

In a hypotonic solution, cells are excited (Lang, et al., 1995: "Exposure of aortic strips from guinea-pigs to hypotonic extracellular fluid is followed by marked vasoconstriction..."), but the early excitation is followed by decreased responsiveness (Ohba, et al., 1984: "Exposure of muscle to hypotonic solutions [70% of normal solution] produced initially a transient increase in twitch after which twitch declined below the control level"). Hypertonic solutions tend to produce relaxation in normal muscles, including the aorta (Tabrizchi, 1999), but when muscle function is impaired (especially in the circulatory system, as in shock) they improve contractile function (Elgjo, et al., 1998: "The maximum contraction force measured in isolated right papillary muscles ex vivo was significantly greater in HSD-treated than normal saline-treated animals"). Athletes can lose 4% of their weight by dehydration without decreasing their muscular strength.

Hypothyroidism tends to cause loss of sodium from the blood, and the hyponatremia sometimes leads to a generalized hypotonicity of the body fluids. The thyroid hormone itself functions as an antioxidant, but much of its protective effect against cell damage is probably the result of preventing cell swelling and accelerating the removal of calcium from the cell. (Swelling, like fatigue, causes intracellular calcium to increase.)

The electrical surface charging of lipids in bulk water probably accounts for the increased lipid peroxidation that occurs in fatigue, edema, and hypothyroidism, when water loses its normal partial hydrophobicity. Increased carbon dioxide is known to decrease lipid peroxidation, and its production requires adequate thyroid function.

Thyroid stimulation of oxygen consumption tends to prevent lactic acid production, because it keeps the cytoplasm in a state of relative oxidation, i.e., it keeps the concentration of NAD+ hundreds of times higher than that of NADH. NADH is required for the conversion of pyruvate to lactate. It is also the source of reducing potential in many kinds of toxic redox cycling, that generate lipid peroxides, and it maintains the sulfhydryl system, involving the balance of reduced glutathione with the sulfhydryl-disulfide system of protein bonds, which governs the cell's electronic state and affects its balance of hydrophobicity and hydrophilicity.

The harmful lipid oxidation interferes with energy production and regulatory processes, and is responsible for some of the prolonged effects of fatigue, swelling, and hypothyroidism. These lingering effects of lipid oxidation are undoubtedly amplified by the presence of larger amounts of unstable polyunsaturated fats, as the energy demands of the fatigued state mobilize free fatty acids from the tissues.

One of the oldest tests for hypothyroidism was the Achilles tendon reflex test, in which the rate of relaxation of the calf muscle corresponded to thyroid function--the relaxation is slow in hypothyroid people. Water, sodium and calcium are more slowly expelled by the hypothyroid muscle. Exactly the same slow relaxation occurs in the hypothyroid heart muscle, contributing to congestive heart failure, because the

semi-contracted heart can't receive as much blood as the normally relaxed heart. The hypothyroid blood vessels are unable to relax properly, contributing to hypertension. Hypothyroid nerves don't easily return to their energized relaxed state, leading to insomnia, paresthesias, movement disorders, and nerves that are swollen and very susceptible to pressure damage.

With aging, hypothyroidism, stress, and fatigue, the amount of estrogen in the body typically rises. Estrogen is catabolic for muscle, and causes systemic edema, and nerve excitation. It weakens muscle contraction in the bladder, although it lowers the threshold for stimulation of sensation and contraction (Dambros, et al., 2004). This is the pattern that causes people to wake up frequently, to pass a small amount of urine. (Progesterone has the opposite effect in the urinary bladder, raising the threshold of response, but strengthening contraction, as it does in the gallbladder.) Estrogen lowers stimulation threshold in the gallbladder, as it does in the brain. Part of its excitatory action might be the result of increased hypotonic tissue water, but its effects on nerve thresholds are practically instantaneous.

In 1971 and '72, I gave some of the reasons for thinking that estrogen's biological effects result from its direct effects on cell water, causing it to become more like bulk (high dielectric) water. For example, NMR (spin echo) of estrogen treated uterus and of the uterus from an old animal were closer to bulk water than that of a young animal. Estrogen, like fatigue or excessive oxygen, slows nerve conduction.

Lactic acid production increases with fatigue, aging, hypothyroidism, estrogen excess, and other inefficient biological states. Its presence, when oxygen is available, indicates that something is interfering with efficient oxidative energy metabolism. Ammonia, free fatty acids, and various inflammatory cytokines are also likely to increase in those stress states.

A dangerously high level of ammonia in the blood (hyperammonemia) can be produced by exhaustive exercise, but also by hyperbaric oxygen (or a high concentration of oxygen), by high estrogen, and by hypothyroidism. It tends to be associated with an excess of lactic acid, probably because ammonia stimulates glycolysis. Excess oxygen, like hypothyroidism, is equivalent to "hyperventilation," in producing an abnormally low level of carbon dioxide in the blood. The Krebs cycle, during stress, is limited by the unavailability of carbon dioxide. These factors result in the waste of glucose, turning it into lactic acid, rather than carbon dioxide and energy. In these ways, the metabolism of fatigued muscle (or any cell under stress) is similar to tumor metabolism.

Hyperammonemia disturbs excitatory processes, and can cause seizures, as well as stupor, and is probably involved in mania and depression. Lithium happens to complex electronically with ammonia, and I think that accounts for some of its therapeutic effects, but carbon dioxide is the main physiological factor in the elimination of ammonia, since it combines with it to form urea. The changes in cell water in the excited/fatigued state represent an increase in the water's "structural temperature," and that would imply that less carbon dioxide could remain dissolved during excitation.

Eating sugar and using caffeine, which increases the oxidation of sugar (Yeo, et al., 2005), can reduce fatigue, both subjectively and objectively. Metabolically, they increase the production of carbon dioxide. Increasing sugar decreases the liberation and use of fatty acids, and by a variety of mechanisms, helps to lower the production of ammonia, lactate, and inflammatory cytokines. (Lactic acid, in combination with acidosis and free phospholipids, can interfere with efficient cell functions [Pacini and Kane, 1991; Boachie-Ansah, et al., 1992].) Free fatty acids release tryptophan from albumin, contributing to the formation of serotonin, which increases the sense of fatigue.

Aspirin and niacin help to prevent fatigue symptoms, and to prevent many of the harmful systemic oxidative after-effects. (Both are antilipolytic; aspirin uncouples mitochondria.)

Uncoupling of mitochondrial oxidative metabolism from ATP production helps to consume the sugar which otherwise would be diverted into lactic acid, and converts it into carbon dioxide instead. Mild hypoxia, as at high

altitude, suppresses lactic acid production ("the lactate paradox"), and increases the amount of carbon dioxide in tissues.

Aspirin and thyroid (T3) increase uncoupling. A drug that used to be used for weight reduction, DNP, also uncouples mitochondrial metabolism, and, surprisingly, it has some of the beneficial effects of thyroid and aspirin. It stimulates the consumption of lactic acid and the formation of carbon dioxide.

The squirrel monkey, which on average weighs about 2 or 3 pounds as an adult, lives much longer than other mammals of its size, usually about 20 years, as long as 27. It has an extremely high rate of oxygen consumption. This is probably the result of natural uncoupling of the mitochondria, similar to that seen in long-lived mice. Mice with 17% higher resting oxygen consumption lived 36% longer than slow respiring mice of a related strain (Speakman, et al., 2004).

Living at a high altitude, people tend to eat more and stay leaner than when they live near sea level. Apparently, their mitochondria are relatively uncoupled, and they have more mitochondria, which would partly account for their lower production of lactic acid during muscular exertion. Increased thyroid activity, too, tends to increase mitochondrial mass, as well as their uncoupling.

Most of the things that we think of as fatigue result from disturbances of the hydration of cells, whose sensitivity, composition, and structure change according to the extent of the disturbance. The hydration is governed by the cells' "electrical" properties, which are regulated by internal metabolic processes and by systemic processes. When cellular fatigue reaches a certain point, only the interactions of all the organs can restore stable cellular structure and functions. The liver eliminates lactic acid and ammonia, the adrenals and gonads provide stabilizing steroids, and the brain alters activity and behavior, in ways that can reverse most of the effects of fatigue.

But, when the tissues contain large amounts of polyunsaturated fats, every episode of fatigue and prolonged excitation leaves a residue of oxidative damage, and the adaptive mechanisms become progressively less effective. When the most powerful adaptive mechanisms, such as the timely synthesis of progesterone, pregnenolone, DHEA, T3, and the inhibitory transmitters, GABA and glycine, fail, then some of the primitive defense mechanisms will become chronically activated, and even sleep may fail to restore normal cellular water and metabolism. Hyperventilation often becomes a problem, making capillary leakiness worse.

Water in the body occupies three major compartments--blood vessels, extracellular matrix, and the moist cell substance itself--and its condition in each compartment is a little different, and subject to variation. There are no textbooks in use in the U.S. that treat intracellular water scientifically, and the result is that physicians are confused when they see patients with edema or with disturbances in blood volume. It rarely occurs to physicians to consider disturbances of water distribution in problems such as chronic fatigue, fibromyalgia, sleep disturbances, frequent urination, slow bladder emptying, anxiety, paresthesia, movement disorders, the tunnel syndromes, or even slowed thinking, but "intracellular fatigue" leading to over-hydration is probably the central problem in these, and many other degenerative and inflammatory problems.

The improvements in cell functions and water distribution that are inversely related to oxygen pressure, and directly related to carbon dioxide, won't be discussed in medical textbooks until they have given up the idea of membrane-regulated cells.

The "treatment" for intracellular fatigue consists of normalizing thyroid and steroid metabolism, and eating a diet including fruit juice, milk, some eggs or liver, and gelatin, assuring adequate calcium, potassium, sodium, and magnesium, and using supplements of niacinamide, aspirin, and carbon dioxide when necessary. Simply increasing carbon dioxide decreases lactic acid and ammonia, increases GABA (the sleep improving nerve inhibitor), and regulates mineral and water disposition.

One of the outcomes of the study of the physiology of fatigue is that it leads to a better understanding of cells in general, and offers some new insights into aging, inflammation, and a variety of stress-related diseases.

Regeneration and degeneration:

Types of inflammation change with aging

For about 100 years it has been popular to explain the degenerative diseases as the result of mutations in the genes, a slow accumulation of "somatic mutations," as opposed to the "germ cell mutations" that are involved in Huntington's chorea and sickle cell anemia. Some people explained all the changes of aging on the same basis, but 50 years ago, the somatic mutation theory of aging was clearly shown to be false. The gene-mutation theory of cancer is more persistent, but the work of people like Harry Rubin has made it clear that functional changes in cells that are becoming cancerous destabilize the chromosomes and cause defects to appear in the genes, rather than the reverse.

Older ways of understanding aging and degenerative disease are now returning to the foreground. The developmental interactions of the organism with its environment, and the interactions of its cells, tissues, and organs with each other, have again become the focus of biological aging research. In place of the old belief that "we are defined and limited by our genes," the new perspective is showing us that we are limited by our environment, and that our environment can be modified. As we react to unsuitable environments, our internal environments become limiting for our cells, and instead of renewing themselves, repairing damage, and preparing for new challenges, our cells find themselves in blind alleys. Looking at aging in this way suggests that putting ourselves into the right environments could prevent aging.

A bird developing inside its egg shell illustrates the way organs and the environment interact. The chicken created a very good environment for the early development of its young. When the egg is formed, it contains everything needed to produce a chicken, except for oxygen and a steady warm temperature. But before the chick's body has finished developing, using yolk fat for energy, the glucose contained in the egg has been consumed, and at that point the chick's brain stops growing. A researcher who knew that brain growth in other kinds of animal requires glucose, injected glucose (or glycine) into the developing eggs when the original glucose had been depleted. The supplemental glucose allowed the chick's brain to continue growing until it hatched. These chicks had larger brains, containing more numerous cells. The same experimenters also found that progesterone increases brain size, while corticosterone decreases it. Although the egg is a very good environment for the development of chickens, these experiments showed that it isn't the best that can be achieved. If the hen's environment had been different, it might have been able to provide as much glucose and progesterone as the experimenters did.

Mammals were able to develop bigger brains than birds, by gestating their offspring internally, allowing a continuous supply of nutrients, such as glucose, and hormones such as progesterone. But the environment of the mother still can profoundly affect the development of the offspring, by influencing her physiology.

Another factor involved in developing a large brain is the metabolic rate, which is closely associated with the temperature. Birds have larger brains relative to their bodies than reptiles do, and birds maintain a consistently high body temperature, sometimes as high as 110 degrees F, while reptiles' temperature varies somewhat according to the temperature of their surroundings and their level of activity. Amphibians have much lower metabolic rates, and are generally unable to live at

the higher temperatures required by reptiles.

The high metabolic rate of a bird, combined with its development inside an egg, means that compromises are made. The high rate of metabolism uses the stored energy rapidly, so the growth of the brain is limited. But their very high body temperature maximizes the effectiveness of that brain. Birds, such as owls, parrots, and crows, that hatch in a less developed, more dependent condition, are able to continue their brain growth, and have larger brains than other birds, such as chickens. In birds and mammals, longevity generally corresponds to brain size and metabolic rate. (For example, a pet crow, Tata, died at the age of 59 in 2006 in New York; parrots sometimes live more than 100 years.) These (altricious) birds are the opposite of precocious, they preserve embryonic or infantile traits into adulthood.

For whole organisms or for single cells, development depends on the adequacy of the environment. Temperature and the quality of nourishment are important, and by thinking about the other special features of the growth processes during gestation, we might be able to find that some of the compromises that are customarily made in our more mature lives aren't necessary.

One way of looking at aging is that it's a failure of regeneration or healing, related to changes in the nature of inflammation.

In childhood, wounds heal quickly, and inflammation is quickly resolved; in extreme old age, or during extreme stress or starvation, wound healing is much slower, and the nature of the inflammation and wound closure is different. In the fetus, healing can be regenerative and scarless, for example allowing a cleft palate to be surgically corrected without scars (Weinzweig, et al., 2002).

Fifty years ago, inflammation was seen as a necessary part of the healing process, but now it is recognized as a cause of heart disease, diabetes, cancer, and aging itself. During the development of the organism, the nature of healing changes, as the nature of inflammation changes. Early in life, healing is regenerative or restorative, and there is little inflammation. In adulthood as the amount of inflammation increases, healing fails to completely restore lost structures and functions, resulting in scarring, the replacement of functional tissue with fibrous tissue. Identifiable changes in the nature of inflammation under different conditions can explain some of these losses of healing capacity. Factors that limit inflammation and fibrosis, while permitting tissue remodeling, could facilitate regeneration and retard aging.

Several cytokines (proteins that regulate cell functions) appear at much higher concentrations in adult tissues than in fetal tissues (PDGF A, three forms of TGF, IGF 1, and bFGF; Wagner, et al., 2007), and when one of these (TGF-beta1) is added to the healing fetus, it produces inflammation and fibrosis (Lanning, et al., 1999). Two prostaglandins, PGE2 and PGF2a, potently produce inflammation in fetal rabbits, but not in adult rabbits. (Morykwas, et al., 1994).

Tissue injury that would produce inflammation in adults causes other signals in the fetus that activate repair processes. When a cell is injured or stressed, for example when deprived of oxygen, it becomes incontinent, and releases ATP into its surroundings. The extracellular ATP, and its breakdown products, ADP, AMP, adenosine, and inorganic phosphate or pyrophosphate, stimulate cells in various ways. ATP causes vasodilation, increasing circulation, and usually signals cells to divide, and can activate stem cells (Yu, et al., 2010) The lactic acid produced by distressed cells also has signalling effects, including vasodilation and stimulated division. Stressed cells digest their own proteins and other structural materials (autophagy), and the breakdown products act as signals to guide the differentiation of their replacement cells. Mobile phagocytes, ingesting the material of decomposing cells, are essential for guiding tissue restoration.

In adults, prostaglandins are known to be involved in many of the harmful effects of inflammation. They are formed from the polyunsaturated fats, linoleic acid and arachidonic acid, which we are unable to synthesize ourselves, so the adult's exposure to the prostaglandins is influence by diet. Since the fetus is able to synthesize fat from glucose, the newborn animal usually contains a high proportion of saturated fats and their derivatives, such as stearic acid, oleic acid, and Mead acid, which can be synthesized from glucose or amino acids. Newborn calves have very little

polyunsaturated fat in their tissues, but even the small percentage of PUFA in milk causes its tissues to gradually accumulate a higher percentage of PUFA as it matures. The fatty acids of newborn humans, and other non-ruminants, reflect their mothers' diets more closely, but Mead acid is still present in human newborns (Al, et al., 1990). In a study of prenatal learning (habituation rate), the experimenters found that the relative absence of the supposedly essential fatty acids improved the short term and long term memory of the fetus (Dirix, et al., 2009). The size of the baby was found to be negatively associated with the highly unsaturated fatty acids DHA and AA (Dirix, et al., 2009), showing a general growth-retarding effect of these environmentally derived fats.

The embryo or fetus is enclosed in a germ-free environment, so it doesn't need an "immune system" in the ordinary sense, but it does contain phagocytes, which are an essential part of development, in the embryo, as well as in the adult (Bukovky, et al., 2000). They are involved in removing malignant cells, healing wounds, and remodeling tissues. In adults, the long-chain omega-3 fatty acids such as DHA are known to be immunosuppressive, but in tests on monocytes from the umbilical cord blood of newborns, the highly unsaturated fatty acids kill the monocytes that are so important for proper development and regeneration (Sweeney, et al., 2001), and interfere with signals that govern their migration (Ferrante, et al., 1994). DHA is now being sold with many health claims, including the idea that adding it to baby formula will improve their eyesight and intelligence. As the consumption of PUFA has increased in the US and many other countries, the incidence of birth defects has increased. The formation of excessive amounts of prostaglandin, or killing macrophages, among other toxic effects, might be responsible for those visible anatomical changes during growth, as well as for the subtler loss of regenerative capacity.

In the adult, the PUFA and prostaglandins are known to increase collagen synthesis. Serotonin and estrogen, which interact closely with PUFA, promote collagen synthesis and fibrosis. In the fetus, hyaluronic acid, rather than collagen, is the main extracellular material in wound repair (Krummel, et al., 1987). Both it and its decomposition products have important regulatory "signal" functions in wound healing (Gao, et al., 2008), inflammation, and cell differentiation (Krasinski and Tchórzewski, 2007).

Prostaglandins also inhibit local cell division (observed in the cornea, Staatz and Van Horn, 1980), shifting responsibility for tissue repair to mobile cells, for example stem cells from the blood. PUFA also interfere with the turnover of collagen by inhibiting proteolytic enzymes that are necessary for tissue remodeling. These are among the changes that characterize scar formation, rather than the scarless regeneration that can occur in the fetus. They also occur throughout the body with aging, as part of a progressive fibrosis.

Besides minimizing dietary PUFA, other things are known that will reduce the fibrosis associated with injury, inflammation, or aging. Thyroid hormone, progesterone, and carbon dioxide all reduce inflammation while facilitating normal tissue remodeling. Fibrosis of the heart and liver, which are often considered to be unavoidably progressive, can be regressed by thyroid hormone, and various fibroses, including breast, liver, and mesentery, have been regressed by progesterone treatment.

The thyroid hormone is necessary for liver regeneration, and the ability of the thyroid gland itself to regenerate might be related to the also great ability of the adrenal cortex to regenerate--the cells of these endocrine glands are frequently stimulated, even by intrinsic factors such as T3 in the thyroid, and seem to have an intrinsic stem-cell-like quality, turning-over frequently. Secretion of stimulating substances is probably one of the functions of macrophages in these glands (Ozbek & Ozbek, 2006) The failure to recognize the glands' regenerative ability leads to many inappropriate medical treatments.

The amount of disorganized fibrous material formed in injured tissue is variable, and it depends on the state of the individual, and on the particular situation of the tissue. For example, the membranes lining the mouth, and the bones and bone marrow, and the thymus gland are able to regenerate without scarring. What they have in common with each other is a relatively high ratio

of carbon dioxide to oxygen. Salamanders, which are able to regenerate legs, jaw, spinal cord, retina and parts of the brain (Winklemann & Winklemann, 1970), spend most of their time under cover in burrows, which besides preventing drying of their moist skin, keeps the ratio of carbon dioxide to oxygen fairly high.

The regeneration of finger tips, including a well-formed nail if some of the base remained, will occur if the wounded end of the finger is kept enclosed, for example by putting a metal or plastic tube over the finger. The humidity keeps the wound from forming a dry scab, and the cells near the surface will consume oxygen and produce carbon dioxide, keeping the ratio of carbon dioxide to oxygen much higher than in normal uninjured tissue.

Carbon dioxide is being used increasingly to prevent inflammation and edema. For example, it can be used to prevent adhesions during abdominal surgery, and to protect the lungs during mechanical ventilation. It inhibits the formation of inflammatory cytokines and prostaglandins (Peltekova, et al., 2010, Peng, et al., 2009, Persson & van den Linden, 2009), and reduces the leakiness of the intestine (Morisaki, et al., 2009). Some experiments show that as it decreases the production of some inflammatory materials by macrophages (TNF: Lang, et al., 2005), including lactate, it causes macrophages to activate phagocytic neutrophils, and to increase their number and activity (Billert, et al., 2003, Baev & Kuprava, 1997).

Factors that are associated with a decreased level of carbon dioxide, such as excess estrogen and lactate, promote fibrosis. Adaptation to living at high altitude, which is protective against degenerative disease, involves reduced lactate formation, and increased carbon dioxide. It has been suggested that keloid formation (over-growth of scar tissue) is less frequent at high altitudes (Ranganathan, 1961), though this hasn't been carefully studied. Putting an injured arm or leg into a bag of pure carbon dioxide reduces pain and accelerates healing.

In aging, the removal of inactive cells becomes incomplete (Aprahamian, et al., 2008). It is this removal of cellular debris that is essential for regenerative healing to take place. Degenerating tissue stimulates the formation of new tissue, but this requires adequate cellular energy for phagocytosis, which requires proper thyroid function. "Hyperthyroidism" has been shown to accelerate the process (Lewin-Kowalik, et al., 2002). The active thyroid hormone, T3, stimulates the removal of inactive cells (Kurata, et al., 1980).

Regenerative healing also requires freedom from substances that inhibit the digestion of the debris. The great decline in proteolytic autophagy that occurs with aging (Del Roso, et al., 2003) can be reduced by inhibiting the release of fatty acids. This effect is additive to the antiaging effects of calorie restriction, suggesting that it is largely the decrease of dietary fats that makes calorie restriction effective (Donati, et al., 2004, 2008).

Niacinamide is a nutrient that inhibits the release of fatty acids, and it also activates phagocytic activity and lowers phosphate. It protects against the development of scars in spinal cord injuries, facilitates recovery from traumatic brain injury, and accelerates healing generally. While it generally supports immunity, it's protective against autoimmunity. It can cause tumor cells to either mature or disintegrate, but it prolongs the replicative life of cultured cells, and protects against excitotoxicity.

The amounts needed seem large if niacinamide is thought of as "vitamin B3," but it should be considered as a factor that compensates for our unphysiological exposure to inappropriate fats. Aspirin and vitamin E are other natural substances that are therapeutic in "unnaturally" large amounts because of our continual exposure to the highly unsaturated plant-derived n-3 and n-6 fats.

When animals are made "deficient" in the polyunsaturated fatty acids, their wounds heal, with normal or accelerated collagen synthesis, and with more vigorous collagen breakdown (Parnham, et al., 1977). Their blood vessels are more resistant, preventing shock that would otherwise be caused by many factors. All phases of development, from gestation to aging, are altered by the presence of the unsaturated fats, and these effects correspond closely to the loss of the regenerative capacity, the ability to replenish and restore tissues.

If the very small amounts of polyunsaturated fats

reaching the fetus can retard growth and brain development (Liu and Borgman, 1977; Borgman, et al., 1975) and function, it is apparently acting on some very important biological processes. The toxic effects of PUFA seen in the animal studies probably have their equivalent in humans, for example the association of childhood hyperactivity with a smaller brain. The incidence of the attention deficit-hyperactivity disorder is increasing in the US, somewhat faster among girls than boys (Robison, et al.,2002). In schizophrenic teenagers, the brain shrinks, suggesting an interaction of the hormones of puberty with environmental toxins or deficiencies. The progressive accumulation of much larger amounts of these fats later in life, especially after the rate of growth decreases, could be expected to cause even greater interference with those processes of development and function.

All tissues age, but the brain might be the least ambiguous organ to consider. The aging brain often shrinks, and becomes more susceptible to excitotoxicity, which kills brain cells. Degenerative brain diseases, such as Huntington's chorea and Creutzfeld-Jacob disease, have been compared to the dementia of pellagra, in which chorea and other excitatory processes are obvious. (Anti-glutamatergic drugs are beginning to be used therapeutically, to restore some inhibitory balance in the degenerating brain.)

Pellagra occurs about twice as often in women as in men, and this is because estrogen activates an enzyme that alters metabolism of tryptophan, blocking the formation of niacin. The alternative products include the excitotoxin, quinolinic acid, and some carcinogens. Progesterone inhibits the activity of that enzyme. **Progesterone also lowers brain serotonin (Izquierdo, et al., 1978), decreases the excitatory carcinogens (Moursi, et al., 1970) and increases the formation of niacin (Shibata, et al., 2003) The polyunsaturated fats, DHA, EPA, and linoleic acid activate the conversion of tryptophan to quinolinic acid (Egashira, et al., 2003, 2004), and inhibit the formation of niacin (Egashira, et al., 1995).**

The normal pathway from tryptophan to niacin leads to formation of the coenzyme NAD, which is involved in a great variety of cellular processes, notably energy production, the maintenance of the cellular differentiated state by regulating gene expression, and the activity of phagocytes.

Glucose and niacinamide work very closely with each other, and with the thyroid hormone, in the maintenance and repair of cells and tissues. When one of these energy-producing factors is lacking, the changes in cell functions -- a sort of pre-inflammatory state -- activate corrective processes. Energy depletion itself is an excitatory state, that calls for increased fuel and oxygen. But when cells are exposed to PUFA, their ability to use glucose is blocked, increasing their exposure to the fats. Saturated fats activate the pyruvate dehydrogenase enzyme that is essential for the efficient use of glucose, while PUFA block it. (The MRL mouse strain has a high regenerative ability, associated with a retained tendency to metabolize glucose rather than fatty acids.) The negative energetic effects of PUFA include interfering with thyroid and progesterone. The energy resources are suppressed, at the same time that the inflammatory signals are amplified, and many regulatory pathways (including the replenishment of NAD from tryptophan) are diverted.

In the fetus, especially before the fats from the mother's diet begin to accumulate, signals from injured tissue produce the changes that lead quickly to repair of the damage, but during subsequent life, similar signals produce incomplete repairs, and as they are ineffective they tend to be intensified and repeated, and eventually the faulty repair processes become the main problem. Although this is an ecological problem, it is possible to decrease the damage by avoiding the polyunsaturated fats and the many toxins that synergize with them, while increasing glucose, niacinamide, carbon dioxide, and other factors that support high energy metabolism, including adequate exposure to long wavelength light and avoidance of harmful radiation. As long as the toxic factors are present, increased amounts of protective factors such as progesterone, thyroid, sugar, niacinamide, and carbon dioxide can be used therapeutically and preventively.

Hepatic alpha-amino-beta-carboxymuconate-epsilon-semialdehyde decarboxylase (ACMSD; formerly termed picolinic carboxylase) [EC4.1.1.45] plays a key role in regulating NAD biosynthesis and the generation of quinolinate (quinolinic acid) from tryptophan. Quinolinate is a potent endogenous excitotoxin of neuronal cells. We previously reported that ingestion of fatty acids by rats leads to a decrease in their hepatic ACMSD activity. However, the mechanism of this phenomenon is not clarified. We previously purified ACMSD and cloned cDNA encoding rat ACMSD. Therefore, in this study, we examined the differential effect of fatty acids on ACMSD mRNA expression by Northern blot. Moreover, we measured quinolinic acid concentration in rats fed on fatty acid. When diets containing 2% level of fatty acid were given to male Sprague-Dawley rats (4 weeks old) for 8 days, long-chain saturated fatty acids and oleic acid did not affect ACMSD mRNA expression in the liver. Eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) strongly suppressed the liver ACMSD mRNA expression. In **rats fed with high linoleic acid diet for 8 days, serum quinolinic acid was significantly increased as compared with the rats fed on a fatty acid-free diet under the condition of the approximately same calorie ingestion.** These results suggest that the transcription level of ACMSD is modulated by polyunsaturated fatty acids, and suppressive potency of ACMSD mRNA is n-3 fatty acid family>linoleic acid (n-6 fatty acid)>saturated fatty acid. Moreover, this study provides the information that a high polyunsaturated fatty acid diet affects the production of quinolinic acid in serum by suppressing the ACMSD activity.

"PUFAs modulate apoptosis of certain tumour cells and cell lines. Monocytes, which are major effector cells of the innate immune system, play a central role in the initiation, development, and outcome of the immune response. They are crucial in the defence against invading pathogens and are involved in the lysis of infected or malignant cells, wound healing, repair, and remodeling of tissues. In the present study we investigated whether PUFAs might evoke apoptosis in newborn monocytes." "In the absence of fatty acids, 30 +/- 4% of control cord monocytes underwent apoptosis or necrosis after 24 h incubation. At a concentration of 50 microM, none of the PUFAs had a significant effect on monocyte cell death, **but at a dose of 100 microM, DHA resulted in 60 +/- 4% cell death ($P < 0.05$) while the other PUFAs had no significant effect. In contrast, at higher concentrations (200 microM), all the PUFAs significantly increased monocyte cell death (AA: 70 +/- 5%, DHA: 86** +/- 2%, EPA: 70 +/- 4%). PUFAs thus exert a potent influence on cord monocyte cell survival in vitro. Their effect is dose-dependent and DHA appears to be the most potent of the fatty acids tested. The influence of PUFAs on neonatal monocyte-cell survival suggests a novel mechanism whereby PUFAs may modulate the immune response."

Autoimmunity

The thymus gland is important for growth and fertility, but it is now considered to be an important regulator of the immune system. As the gland shrinks with aging, the incidence of "autoimmune diseases" increases, possibly because the regulatory functions of the gland have been lost.

It has been shown that radiation, polyunsaturated fatty acids, estrogens, and heavy metals and other toxins including dioxins damage the thymus gland, and can produce immunodeficiency. These stressors also stimulate the "autoimmune" antibodies.

Estrogen shrinks the thymus and blocks NK cells, and blocks cell division in thymic cells. Thyroid stimulates regeneration of the thymus, even after age-related atrophy. Progesterone protects against the thymic atrophy produced by stress and cortisol, and promotes thyroid's effects, and protects against many of the conditions that are called "autoimmune." Estrogen creates both immunodeficiency and autoimmune degenerative conditions.

Hypothyroidism causes the thymus gland to atrophy (Abou-Rabia and Kendall, 1994), partly because the thyroid hormone itself is essential for the maintenance of the gland, and also because hypothyroidism is likely to be accompanied by excessive levels of estrogen and cortisol.

Polyunsaturated fatty acids interfere with the formation of the thyroid hormones, by preventing the coupling reaction, which converts iodotyrosine residues into iodothyronine residues in the thyroglobulin. The resulting abnormal thyroglobulin is antigenic.

Animals that are fed diets that completely lack the polyunsaturated fatty acids appear to be free of the autoimmune diseases: their tissues can even be transplanted into other animals with less antigenicity than is normal, so the dietary polyunsaturated fatty acids seem to be involved in the development of the abnormally increased antigenicity of the various autoimmune degenerative diseases.

Several years ago, I wrote about Metchnikov's theory of immunity, based on the role of the phagocyte in the organism's ordinary growth, and I also argued that inflammation was a pathological reaction, rather than being a healthy part of a defensive immune system. Since then, the role of inflammation has been recognized in heart and circulatory disease, Alzheimer's disease, and other diseases, and even in obesity, diabetes, depression, and osteoporosis, so that now it isn't a universal medical reflex to think of inflammation as a purely normal physiological response. However, the history of treating inflammation as part of "the immune system" has left a residue of medical ideology, in which a pathogenic organism must be invoked as the cause of any inflammation, even though the concept of "sterile inflammation" has a strong foundation of evidence.

Metchnikov's view, that the "immune system" is a constructive part of normal physiology, combined with the idea of inflammation as a pathological hindrance to normal functioning and development, forms the framework for a major reconsideration of the functions of antibodies, the thymus gland, lymphocytes, and other parts of "the immune system." A few people (Jamie Cunliffe and Polly Matzinger, for example) are working on this new paradigm of "immunity," challenging the "assumption that the immune system . . . has evolved to find, kill and eliminate foreign organisms." If they are right, then all of medical thinking about immunity since Metchnikov's ideas were discarded has been, effectively, an attack against a full and proper understanding of the nature of the organism, and specifically has led to a deep misunderstanding of growth, regeneration, aging, cancer, and the

functions of nerves, hormones, and tissue interactions.

A pathogen is usually defined as an organism or a substance that causes tissue damage. I think the definition should be "a substance or process that causes tissue damage," to include the pathogenic effects of malnutrition, stress, and radiation, for example. The consequences of tissue damage have to be distinguished from the causes of tissue damage. The failure to distinguish cause and effect has led to many foolish medical theories.

The new orientation toward the immune system is that its main function is to clean up the debris created by developmental processes (such as the elimination of red blood cells, or the regression of the tadpole's tail), or by injury, and to prepare the system for recovery or regeneration. This orientation brings together ideas from developmental biology and immunology in a very encouraging way. For example, a recent study shows that "autoimmune" antibodies are involved in brain repair after traumatic injury. (Hofstetter, et al., 2003.)

The example of the tadpole's tail provides a metaphor that might be useful in understanding the ways in which hormones and the immune system interact in mammals and people. Without the thyroid hormone, a tadpole keeps its tail, and fails to turn into a frog, though it keeps growing. The thyroid hormone causes the animal to progress to a higher stage of development, in which it has a higher metabolic rate and uses lungs rather than gills. The phagocytic cells rapidly consume the structures that were appropriate for the lower stage of development and metabolism.

I think we can see analogous processes in the functioning of our immune system. When cells in any part of the body aren't able to maintain an efficient energy metabolism, they tend to be replaced by new, more active cells, and the debris of the old cells is removed by phagocytosis, often without detectable inflammation. Stimulation and adaptation are always causing remodeling of our bodies, with bones growing along lines of stress, areas of the brain expanding with learning, and organs such as the intestine and liver modifying their metabolism according to diet and exposure to toxins.

Inflammation, atrophy, or tumefaction can occur when some part of the regenerative and developmental process is defective. A failure of energy metabolism can be seen in each of these types of problem. Usually, prolonged inflammation leads to atrophy and fibrosis, which in turn increases the likelihood that a tumor will develop.

Two organs that can change their mass greatly in a short period of time are the thyroid and the thymus.

The thyroid can be functionally suppressed, and, with stimulation, return to full activity within a few hours. If it is stimulated continuously, it can increase its mass greatly in a few days. The thymus can lose most of its mass in a few hours.

The remarkable ability of the thymus gland to shrink rapidly when it's exposed to estrogen or stress or cortisol is very probably related to the fact that "cleaning up messes" is a primary function of many of the cells that constitute it.

Most of the cells of the thymus are very dependent on sugar metabolism, and this is disturbed by stress, cortisol, estrogen, and some kinds of fat. Even under normal conditions, there is a rapid turnover of its cells. Many of the cells that make up the thymus, like leukocytes generally, are highly sensitive to anything that limits their energy.

These changes in the size and composition of the thyroid and thymus glands involve some of the biochemical processes that are involved in the developmental changes in tadpoles and frogs.

Inflammation occurs when the production of debris is too rapid for its quiet removal, as when energetic process fail, or when certain specialized organisms interact destructively with the tissues. The characteristic changes in metabolism, a shift toward the production of lactic acid and the breakdown of protein, are probably as much the cause of inflammation, as its effect.

Estrogen is an important regulator of energy metabolism, and it is therefore crucially involved in the diseases known as "autoimmune diseases."

Progesterone, thyroid, and various nutrients including vitamin E, oppose the actions of

estrogen, and so have a role in the prevention of the "autoimmune diseases."

These diseases include rheumatoid arthritis, multiple sclerosis, Sjogren's syndrome, Devic's optic neuritis, cystitis, and various types of hepatitis and nephritis and pancreatitis.

Aging and stress are estrogenic, and this estrogen effect leads to atrophy of the thymus, combined with inflammation. The associated cortisol excess decreases the inflammation, but aggravates the disregulation of the immune system. Serotonin is another stress-related factor that produces involution of the thymus (Bliznakov, 1980).

The thymus gland permits immune cells to mature and to become organized. It is a major factor in the regulation of the cells that produce antibodies, the B (bone marrow derived) lymphocytes, and when the thymus is chronically damaged, the production of antibodies tends to increase, but without the sensitive control the thymus provides. Thymus-type cells are produced not just in the thymus, but also in other organs, especially the liver.

In the young organism, the disruption of a tissue exposes a variety of antigens from the differentiated cells. Antibodies that are formed to these antigens have two very different functions. They stimulate the removal of the defective cells and debris, and they locally obscure the specifically differentiated tissue components, creating a sort of vacuum to be filled by the multiplication of undifferentiated "stem" cells, which repair the damaged region.

One line of research in developmental biology emphasizes the innate tendency of cells to grow and multiply, with differentiation and growth inhibition being the subsequent result of interactions with their environment.

For many years, researchers such as Szent-Gyorgyi searched for general or specific inhibitors of cellular multiplication. Szent-Gyorgyi gave the name "retin" to a molecule that he thought could restrain cancer growth. Leonell Strong studied liver extracts, and found several anticancer agents. W.S. Bullough extracted materials that were tissue specific, that he thought might synergize with adrenaline in restraining tissue growth.

About 50 years ago, an experiment with developing frogs' eggs encouraged this line of research. The experimenter found that when the juice extracted from a particular tissue was added to the water in an aquarium where frog eggs were starting to develop, the developing embryo had a deficiency of that particular tissue, and its development would stop when the absence or deficiency of that tissue became limiting. In rats, a similar organ-specific substance had been suggested by removing part of the liver of one rat of a pair that shared the same blood supply. The livers of both animals grew until the total mass was appropriate for two animals, but the operated liver stopped growing prematurely, apparently because a circulating growth inhibiting substance reached a certain level. Bullough's term "chalone" has been generally accepted as the name for such growth inhibiting substances.

I suspect that the immune system, and the "autoantibodies," can have a function complementary to that of the chalones, possibly by blocking the release of chalones.

In 1970, I. Hellstrom and K.E. Hellstrom showed that cancer growth is promoted by an antibody, and later they showed that antagonists to that antibody would allow the cancer to be suppressed. Their work is still progressing, and it is probably relevant to both the chalone theory, and to the processes of autoimmunity and tissue regeneration. Proper control in the immune system is very closely associated with the processes that maintain a proper balance between tissue growth and tissue atrophy. Too much of an anti-chalone agent would produce a tumor, but too little would lead to atrophy when stress-damaged tissues weren't replaced.

Recent work by M. Bissell and V. Weaver shows results parallel to the Hellstroms', but involving the interactions of cells, extracellular matrix, and antibodies.

The healthy thymus gland, which depends on a properly functioning thyroid gland, is essential for close regulation of the antibody-producing cells. With aging and the various stressors, the immune system tends to over-produce antibodies, as the cell-mediated process become weaker. This is similar to the changes produced by estrogen (for

example, see Ansar Ahmed, et al., 1989). It's generally accepted that the thymus is responsible for preventing the production of autoimmune antibodies. I suspect that its actions are more subtle, and that it is (or can be) involved in developmental and regenerative processes.

Animal studies of autoimmune degenerative diseases show that estrogen promotes autoimmunity, and that progesterone alleviates or prevents some of the typical autoimmune diseases. Their antagonistic effects on the mediators of inflammation are probably responsible, as well as their opposite effects on the activation of retroviruses and stress (or "heat shock") proteins.

Systemic lupus erythematosis, rheumatoid arthritis, and other autoimmune diseases are usually corrected by the combined use of progesterone and thyroid, both of which help to restore the thymus gland.

Although medical people have been taught to believe that aging isn't an estrogenic state, contrary to the clear evidence that estrogen production (by the aromatase enzyme) in many tissues increases with age, an experiment (Greenstein, et al., 1992) has demonstrated that giving an aromatase inhibitor to old rats causes their thymus to regenerate. Now that commercial aromatase-inhibiting drugs are coming onto the market, this experiment should be of considerable interest to people involved in cancer treatment, but its implications are so important that most researchers and therapists will prefer to forget it.

The estrogenic state of old age or of stress (with increased exposure to cortisol) is partly the result of the progressive decrease in thyroid and progesterone, which is closely associated with the decline in respiratory function and mitochondrial efficiency.

The declining energy functions increase the demand for an efficient immune system, especially when we see the immune system as a regulator of tissue repair and restoration.

The accumulation of polyunsaturated fats contributes to all phases of this process of holistic decline, from the decrease of the crucial respiratory enzyme cytochrome c oxidase, through decreased thyroid hormone activity and progesterone activity, to the activation of aromatase and estrogen and the production of tissue antigens by toxic products of lipid peroxidation.

A study in Hawaii found that men who ate tofu were more likely to have dementia and brain atrophy than men who ate a standard "western" diet. Soybeans contain estrogenic chemicals, such as genistein. In Alzheimer's disease brain metabolism is low. Genistein, like other estrogens, causes the thymus gland to atrophy (Yellayi, et al., 2002). Since Alzheimer's disease is now often considered to be an "autoimmune" disease (Grainger and Reckless, 2003; Kellet, et al., 1982; Lal and Forster, 1988; Bradford, et al., 1989), both preventive and curative approaches should probably concentrate on protecting and restoring the energy metabolism and the thymus gland.

Besides the systemic toxic effects of dietary polyunsaturated fats, those fats appear to be a major factor in making tissues susceptible to damage from immunological reactions, since the tissues of rats that are deficient in the "essential fatty acids" are not damaged by antibodies that would seriously injure or kill "normal" tissues. (Takahashi, et al., 1992; Schreiner, et al., 1988). These animals are also resistant to many toxins, including endotoxin.

The unsaturation of tissue lipids increases in aging animals, along with the increased production of estrogen and decreased production of pregnenolone, progesterone, and the T3 component of the thyroid hormone. Autoimmunity increases with aging, as the thymus gland atrophies. A program to prevent or correct autoimmunity should also help to reverse the very generalized inflammatory and atrophic processes of aging. Restoration of tissue lipids (especially cardiolipin, which activates the crucial respiratory enzyme) to the high-energy state of childhood would be a central part of such a program. (See for example Paradies & Ruggiero, 1991; Paradies, et al., 1997.)

Antibodies to cardiolipin are promoted by excess estrogen (Ahmed & Verthelyi, 1993), and this is probably related to estrogen's antirespiratory actions.

Rather than viewing autoimmune diseases as irreversible degenerative conditions, I think they should be viewed as problems of metabolic

energy, processes of self-repair that just need a little support from improved diet and other environmental conditions. (See Hofstetter, et al., 2003).

REFEREBCES

Cell Tissue Res 1994 Sep;277(3):447-55. **Involution of the rat thymus in experimentally induced hypothyroidism.** Abou-Rabia N, Kendall MD. The thymus, as part of the immune-neuroendocrine axis, is greatly influenced by factors from most endocrine glands, especially the thyroid. Antithyroid drugs (carbimazole and methimazole) were used to induce hypothyroidism in rats. Histological and ultrastructural examination of the thymus showed progressive thymic involution after 4 weeks of drug treatment to the end of observations (7 weeks). The involution was characterised by increased thymocyte apoptosis and thymocyte phagocytosis by macrophages. This resulted in thymocyte depopulation, increases in numbers of interdigitating cells, alterations to mainly subcapsular and medullary epithelial cells, an apparent increase of mast cells and collagen in the capsule and septa, and increased numbers of B cells and plasma cells. Lymphoid cells immuno-reactive with MRC OX12 (which detects B cells) were observed within blood vessel walls, suggesting that they may have been moving in and out of the thymus. The administration of drugs causing hypothyroidism, therefore, also caused marked involution of the thymus.

J Autoimmun 1993 Jun;6(3):265-79 **Antibodies to cardiolipin in normal C57BL/6J mice: induction by estrogen but not dihydrotestosterone.** Ahmed SA, Verthelyi D "Autoantibodies against cardiolipin, a phospholipid, have been demonstrated in a variety of pathological states including several autoimmune conditions in humans and in certain lupus-prone mice." "Similarly, estrogen treatment of female mice further augments the incidence and the levels of these autoantibodies. Estrogen-treated mice also have antibodies reactive against other membrane phospholipids including phosphatidylinositol (PI), phosphatidylserine (PS), phosphatidylcholine (PC) and phosphatidylethanolamine (PE)." "To our knowledge, this is the first report on the demonstration of antiphospholipid autoantibodies in normal mice and induction of these antibodies by estrogen."

J Autoimmun 1989 Aug;2(4):543-52. **Estrogen induces the development of autoantibodies and promotes salivary gland lymphoid infiltrates in normal mice.** Ahmed SA, Aufdemorte TB, Chen JR, Montoya AI, Olive D, Talal N "Sex hormones influence the immune system throughout life including postnatal and prenatal stages. For example, we find that administration of estrogen to normal mice markedly augments the ability of CD5+ B cells to express their autoimmune potential by producing increased numbers of plaque-forming cells (APFC) to bromelain-treated mouse erythrocytes (Br-ME)." "We hypothesize that an imbalance of the in utero sex hormone microenvironment critically influences the fetal immune system. **We have termed this influence immunological imprinting.** After birth this imprinting could contribute to immune-mediated disorders. To test this hypothesis, we developed a mouse model in which normal mice were prenatally exposed to estrogens. In preliminary experiments, these mice produced higher numbers of APFC to Br-ME, particularly in the peritoneal cavity cell exudates. Furthermore, mice prenatally exposed to estrogens had accelerated development of autoimmune salivary gland lesions indistinguishable from Sjogren's syndrome (SS) in humans. Further experiments are warranted to confirm these findings. The prenatal effects of estrogen may have relevance for familial and neonatal autoimmune syndromes."

J Immunol 1989 Apr 15;142(8):2647-53. **Estrogen induces normal murine CD5+ B cells to produce autoantibodies.** Ansar Ahmed S, Dauphinee MJ, Montoya AI, Talal N "Females have better humoral immune responses and are more susceptible to autoimmune diseases than males." "The increased autoantibody production in females can be attributed to the effect of estrogen on the immune response because this hormone markedly augments APFC to Br-ME in intact or orchidectomized males. Male hormone had little effect. Importantly, estrogen did not increase the numbers of B or CD5+ B cells but **augmented the ability of B cells to produce this response.** This was verified when a T cell-depleted B cell fraction or fluorescence-activated cell sorter purified CD5+ B cells from estrogen-treated mice proved more efficient in the production of APFC to Br-ME. These results suggest that the number of CD5+ B cells committed to produce autoantibodies to Br-ME is increased under the influence of estrogen. This is the first demonstration that estrogen can augment the production of natural autoantibodies in normal mice. The overall augmented humoral immune responses in females and the **B cell hyperactivity** in female predominant autoimmune diseases appears to be due to estrogen."

Cutis 1978 Mar;21(3):321-5. **Is vitamin E involved in the autoimmune mechanism?** Ayres S Jr, Mihan R

Free Radic Biol Med 2000 Jan 1;28(1):84-90. **Effect of exhaustive exercise on membrane estradiol concentration, intracellular calcium, and oxidative damage in mouse thymic lymphocytes.** Azenabor AA, Hoffman-Goetz L. "Intracellular Ca2+ levels were significantly higher in thymocytes of exercised compared with control mice ($p < .001$). There was a continuous flux of Ca2+ after exercise when cells were monitored in Ca2+ rich medium, with a significant influx between 160 and 200 sec ($p < .001$). Membrane bound estradiol was elevated in thymocytes of exercised compared to control mice ($p < .05$). Immediately after exercise there was a greater release of oxidative products by thymocytes in exhaustively exercised compared with control animals. There was also significant generation of lipid peroxide in thymus of exercised mice ($p < .001$). The findings suggest that exhaustive exercise may stimulate estradiol uptake by receptors on thymocytes, with a possible opening up of estradiol-receptor operated channels for Ca2+ entry into cells. This may have damaging effects on thymic lymphocytes by the triggering of oxidative reactions as determined by higher oxidative product release and greater generation of lipid peroxide."

Am J Pathol 1987 Jan;126(1):103-13 **Dietary fatty acid effects on T-cell-mediated immunity in mice infected with mycoplasma pulmonis or given carcinogens by injection.** Bennett M, Uauy R, Grundy SM. ". . . only mice on the POLY diet were significantly immunosuppressed, and only T-cell-mediated cutaneous sensitivity reactions were affected." "Deliberate infection with Mycoplasma pulmonis resulted in suppressed cutaneous T-cell responses in the POLY group of C3B6F1 mice, and aspirin partially reversed the immunosuppression." "It is tentatively concluded that diets rich in w-6 polyunsaturated diets, while not directly immunosuppressive, do predispose animals to suppression of certain T-cell-mediated immune responses. This immunosuppression can be "triggered" by infection and/or by exposure to carcinogens."

Trends Mol Med 2002 Oct;8(10):469-76. **Thymic regeneration: teaching an old immune system new tricks.** Berzins SP, Uldrich AP, Sutherland JS, Gill J, Miller JF, Godfrey DI, Boyd RL. **Recent studies in mice and humans show that the importance of the thymus extends well beyond the initial seeding of the peripheral T-cell pool.** Although peripheral homeostasis can maintain T-cell numbers, the thymus is the major,

if not the exclusive, source of new T-cell specificities. With age, thymus atrophy dramatically reduces the export of new T cells and predisposes an individual to impaired T-cell function, reduced T-cell immunity, and increased autoimmunity. Thymus atrophy is also the primary obstacle to restoration of the T-cell pool in the aftermath of HIV treatment or lymphoablative therapies. Here, we review thymus T-cell production, with particular attention to the factors that influence thymocyte export, and examine the impact that recent thymic emigrants have on the peripheral pool. In the future, thymic regeneration might become a feasible and potentially powerful approach to rejuvenating a depleted peripheral T-cell pool.

J Rheumatol 1990 Mar;17(3):311-7. **Sex hormone involvement in the induction of experimental systemic lupus erythematosus by a pathogenic anti-DNA idiotype in naive mice.** Blank M, Mendlovic S, Fricke H, Mozes E, Talal N, Shoenfeld Y "We found that injection of the pathogenic idiotype to BALB/c females and orchiectomized males treated with estrogen caused a rapid outburst of the disease 3 months after immunization, while nonestrogen treated mice developed the disease 5 months after immunization. The flare of SLE disease was characterized by raised levels of autoantibodies in the sera to dsDNA, histones, cardiolipin, Sm, RNP, SSA (Ro), SSB (La) and an emergence of high titers of mouse antibody carrying the 16/6 Id. These enhanced antibody levels were associated with an increase in erythrocyte sedimentation rate, proteinuria and leukopenia." "Our data demonstrate the importance of sex hormones on the induction of experimental SLE-like disease in mice with no genetic tendency to autoimmunity."

J Med 1980;11(2-3):81-105. **Serotonin and its precursors as modulators of the immunological responsiveness in mice.** Bliznakov EG. "The evidence of serotonergic-endocrine interrelations with regard to adrenal, thyroid, gonadal and prolactin functions is fast accumulating. Our study extends the importance of those interrelations to some functions of the immune system. **Multiple administration of 5-hydroxytryptamine(serotonin) or its precursor, 5-hydroxy-L-tryptophan(5-HTPH), produces marked depression of T cell dependent, humoral, hemolytic, primary immune response in mice. L-tryptophan, a more distant serotonin precursor, produces slight but significant depression of this immune response." "Administration of serotonin or 5-HTPH causes a marked reduction of the thymus weight. It is reasonable to postulate that the described effects result from the thymus involution which affects the T cell compartment of the immune system."** Since many clinically used drugs affect the serotonin metabolism, the clinical consequences of the resulting alteration of the immunological responsiveness should be considered."

J Steroid Biochem Mol Biol. 2002 Aug;81(4-5):309-17. **Differential activation of the IkappaBalpha and mouse mammary tumor virus promoters by progesterone and glucocorticoid receptors.** Deroo BJ, Archer TK. "To investigate how co-existing steroid receptors regulate gene transcription, we have compared two hormone-responsive promoters in T47D/A1-2 human breast cancer cells expressing both the GR and PR. The promoters chosen were those for the mouse mammary tumor virus (MMTV) and the gene for IkappaBalpha, the inhibitor of the ubiquitous transcription factor, nuclear factor kappa B (NFkappaB). Several differences between glucocorticoid and progestin activation of the IkappaBalpha and MMTV promoters were revealed. Both steroids activated the endogenous IkappaBalpha promoter, while only glucocorticoids activated a stably integrated MMTV promoter. In combination, progestins enhanced glucocorticoid activation of IkappaBalpha, but antagonized glucocorticoid activation of MMTV."

Fertil Steril 1991 Oct;56(4):718-24. **The relationship between in vitro fertilization and naturally occurring antibodies: evidence for increased production of antiphospholipid Autoantibodies.** Fisch B, Rikover Y, Shohat L, Zurgil N, Tadir Y, Ovadia J, Witz IP, Yron I OBJECTIVE: Assessment of possible effects of ovarian stimulation during in vitro fertilization (IVF) treatment cycles on circulating levels of antiphospholipid and antinuclear autoantibodies. DESIGN: The study was performed prospectively. Sera were obtained at three time points along IVF treatment cycle. Levels of autoantibodies directed against nuclear components, mitochondrial antigens, and phospholipids were determined using enzyme-linked immunosorbent assay. PATIENTS: Thirty-five patients, who underwent at least one previous IVF attempt, and 36 age- and sex-matched controls were analyzed. All participants were randomly selected. RESULTS: The mean levels of antiphospholipid (but not antinuclear) autoantibodies in sera from IVF-treated patients were found to be significantly higher than the corresponding values of the control group (for immunoglobulin [Ig]M isotype: anticardiolipin, antiphosphatidyl L-serine; for IgG isotype: anticardiolipin, antiphosphatidyl L-serine, and antiphosphatidylcholine; P less than 0.0001, assessed by Mann-Whitney test). The autoantibody levels remained more or less constant at different time points along the treatment cycle. No correlation with age and number of previous IVF cycles was demonstrated. CONCLUSIONS: Serum levels of antiphospholipid (but not antinuclear) autoantibodies increase after IVF treatment. Based on these preliminary data, it is not yet possible to estimate if the observed changes in autoantibody levels might have any future clinical influence on infertile patients undergoing IVF treatment. Comment in: Fertil Steril 1992 Oct;58(4):863-5.

Cell Mol Life Sci 1998 Oct;54(10):1076-82. **Regulation of B and T cell development by anterior pituitary hormones.** Foster M, Montecino-Rodriguez E, Clark R, Dorshkind K. Hormones produced by the anterior pituitary gland have been implicated in the regulation of primary lymphocyte development. In order to identify endocrine factors involved in that process, several strains of mice with genetic defects resulting in a selective impairment in the production of one or more anterior pituitary-derived hormones have been analysed. This study has resulted in the classification of endocrine hormones into the following four categories: (i) hormones such as prolactin with no apparent effects on primary lymphopoiesis; (ii) anabolic hormones such as growth hormone and insulin-like growth factor-I whose stimulatory effects on primary lymphopoiesis are non-lineage-specific and related to their actions as systemic mediators of growth and/or differentiation; (iii) hormones such as thyroid hormones that have an obligate role in primary B lymphopoiesis; and (iv) hormones such as oestrogens that act as negative regulators of lymphopoiesis.

Schweiz Rundsch Med Prax 2001 Nov 1;90(44):1913-22. **[The environment and autoimmunity--from external causes to inner conflicts]** Gebbers JO. "Autoimmune disorders result from a breakdown of immunologic tolerance leading to an immune response against self-molecules. In most instances the events that initiate the immune response to self-molecules are unknown, but a number of studies suggest associations with environmental and genetic factors and certain types of infections. **The concordance of autoimmune diseases among identical twins is virtually always less than 50%, often in the 25-40% range.** This observation, as well as epidemic clustering of some autoimmune diseases following xenobiotic exposure, reinforces the thesis that autoimmune disease is secondary to both genetic and environmental

factors." "With these comments in mind it is important to note that there have been associations of a number of xenobiotics with human autoimmune disease, including mercury, iodine, vinyl chloride, canavanine, organic solvents, silica, L-tryptophan, particulates, ultraviolet radiation, and ozone." "With the world-wide deterioration of the environment, this is a particular important subject for human health. This is best illustrated by the epidemics of eosinophilic myalgia syndrome with shared characteristics that occurred about 20 years ago. Another example is the toxic oil syndrome of Spain in 1981 involving cooking oil led to both acute and chronic disease as well as formation of auto-antibodies to collagen, DNA, and skeletal muscle. Currently the question is risen whether there is a link between environmental estrogens and autoimmune disorders, especially since these illnesses are reported possibly more frequent."

Physiol Behav 1999 Dec 1-15;68(1-2):169-74. **Effect of estradiol and exercise on lymphocyte proliferation responses in female Mice.** Hoffman-Goetz L. "This study investigated the effect of estradiol exposure and physical exercise on lymphocyte proliferation responses to T and B cell mitogens in female mice." **"In the thymus, there was a significant reduction of proliferation to ConA in the Ovx + E2 animals** relative to the other conditions at both concentrations of mitogen. At 1.0 microg/mL concentration, there was a significant interaction of hormone and exercise treatments. Sham (control) mice given exercise had a higher proliferation response relative to sedentary counterparts, whereas E2 mice did not differ in proliferation responses, irrespective of exercise condition. In the spleen, exposure to high concentrations of estradiol was associated with reduced proliferation responses to both mitogens; there were, however, no main or interaction effects of exercise. These results suggest that high levels of estradiol exposure following ovariectomy in mice significantly reduces lymphocyte blastogenesis responses, and that thymic immunomodulation after acute exercise is masked by the hormonal effect."

J Neuroimmunol 2003 Jan;134(1-2): 25-34. **Autoreactive T cells promote post-traumatic healing in the central nervous system.** Hofstetter HH, Sewell DL, Liu F, Sandor M, Forsthuber T, Lehmann PV, Fabry Z. In general, autoimmune responses are considered harmful to the host. In the best-defined model of autoimmune disease, murine experimental allergic encephalomyelitis (EAE), for example, brain-protein-specific autoimmune responses of both major classes, type-1 and type-2, have been implicated in causing brain pathology. We induced type-1 and type-2 autoimmunity to myelin oligodendrocyte protein (MOG) in C57.BL/6 mice. Instead of using pertussis toxin (PTX) to open the blood-brain barrier (BBB), which is the classic procedure, we set an aseptic cerebral injury (ACI) to see what the consequences of pre-primed, autoreactive type-1 and type-2 memory T cells gaining access to the brain in the course of sterile tissue injury would be. **Neither of these autoimmune response types induced pathology; on the contrary, both accelerated re-vascularization and post-traumatic healing.** The data suggest that induction of either type-1 or type-2 autoimmune responses is not inherently noxious to the host, but can have beneficial effects on tissue repair. Autoimmune pathology may develop only if molecules of microbial origin such as pertussis toxin additionally induce the "infectious nonself/danger" reaction in the antigen-presenting cells (APC) of the target organ itself.

Arch Histol Cytol 1997 Mar;60(1):65-78. **Glucocorticoid-induced thymocyte death in the murine thymus: the effect at later stages.** Ishii T, Nakamura M, Yagi H, Soga H, Kayaba S, Gotoh T, Satomi S, Itoh T. "We report here on kinetics of glucocorticoid-induced murine thymocyte death in vivo by the TUNEL method. TUNEL-positive cells were observed as early as at 2 h after intraperitoneal injection of glucocorticoid." "At 6 to 8 h after the injection, the number of phagocytosed thymocytes per individual macrophage had reached its maximum, and at 8 to 12 h many ruptured macrophages ingesting too many dying thymocytes became noticeable. During the process, no additional macrophages appeared to be mobilized to the thymus. At 6 to 8 h after the injection, however, coincidentally with the fact that macrophages had become unable to further ingest dying lymphocytes, dead cells were left unphagocytosed, and ultimately became "free" positive cells, probably due to some proteolytic process ongoing within the thymus. As late as at 12 h, morphological examination revealed that epithelial cells seemed to begin engulfing thymocytes, almost simultaneously with the start of rupture of the macrophages due to the ingestion of too many thymocytes." "Altogether, these results suggest that: 1) even though thymocytes were exposed to glucocorticoid in vivo, most of them were not TUNEL-positive unless they were phagocytosed; 2) even after most macrophages had ingested too many cells at later stages, macrophages in other locations did not migrate to the thymus; and finally, 3) deletion of damaged thymocytes was also carried out by thymic epithelial cells, though not frequently, at around 12 h and later."

Rinsho Shinkeigaku 1993 Sep;33(9):995-7. **[A case of Hashimoto's encephalopathy with a relapsing course related to menstrual cycle]** Ishii K, Hayashi A, Tamaoka A, Mizusawa H, Shoji S. A case of 43-year-old woman with Hashimoto's encephalopathy who experienced three relapses closely associated with the menstrual cycle is reported. In April 1992, she began to experience occasional tremors in her arms. Three months later, she experienced a generalized seizure and was transferred to our hospital. Hashimoto's thyroiditis was diagnosed on the basis of high thyroid microsomal titer and mild hypothyroidism. Neurological findings in admission included action tremor in both hands, myoclonus in all extremities, cerebellar ataxia, confusion, and hyperreflexia. Cerebrospinal fluid showed elevated protein level without pleocytosis. Electroencephalogram showed diffuse slowing and magnetic resonance imaging of brain was normal. Hashimoto's encephalopathy was diagnosed from these findings. **These episodes of remission and exacerbation were observed during the admission. Her symptoms started at ovulation, worsened during the luteal phase, and improved when menstruation started. After the third relapse, she was treated with oral thyroxine for hypothyroidism and with an estrogen and progesterone combination to regulate the menstrual cycle. Her thyroid function gradually became euthyroid and she did not experience any subsequent relapses. The relation between the relapsing course and menstrual cycle suggests that the periodic alteration of gonadotrophic and/or gonadal hormones or the menstrual regulating center itself in the brain may be an important factor of pathogenetic mechanism of the disorder.**

Transplantation 1989 Jul;48(1):98-102. **Enhancement of immunosuppression by substitution of fish oil for olive oil as a vehicle for cyclosporine.** Kelley VE, Kirkman RL, Bastos M, Barrett LV, Strom, T.B.

Berl Munch Tierarztl Wochenschr 1992 Mar 1;105(3):81-85. **[Modification of lymphoblastic transformation by estradiol, progesterone and corticosterone in vitro].** Kuhn V, Hardegg W "In conclusion, corticosterone, E2 and progesterone showed a dose-dependent influence on lymphoblast transformation of thymocytes and splenocytes and progesterone had opposite effects on corticosterone-induced suppression of blastogenesis in rat lymphocytes, especially in thymocytes."

J Immunol 1990 Mar 15;144(6):2147-51. **The nonobese diabetic mouse model. Independent expression of humoral and cell-mediated autoimmune features.** Lehuen A, Bendelac A, Bach JF, Carnaud C. "Altogether, these results suggest that NOD mice, like other autoimmune strains, **suffer from a genetically inherited defect of B cell regulation resulting in the hyperproduction of natural autoantibodies."**

Int J Immunopharmacol 1984;6(4):287-97. **Mechanisms of estrogen-induced myelotoxicity: evidence of thymic regulation.** Luster MI, Boorman GA, Korach KS, Dieter MP, Hong L. "Mice exposed to pharmacological levels of steroidal and nonsteroidal estrogens including alpha-dienestrol, 17 beta-estradiol, and diethylstilbestrol **demonstrate bone marrow hypocellularity, and decreased numbers of pluipotent hemopoietic stem cells.** Hormones with little estrogenic activity including testosterone and progesterone failed to induce myelotoxicity as did nonestrogenic metabolites of DES." "One of these mechanisms is mediated through the thymus since surgical thymectomy abolished the ability of estrogens to suppress CFU proliferation." "That the initial events in estrogen-induced myelotoxicity may be mediated through a receptor

mechanism was suggested by the ability of antiestrogens to induce antagonism when administered prior to estradiol and the presence of estrogen binding components in lymphoreticular tissues including the thymus and bone marrow. These studies suggest that reduced CFU kinetics observed following estrogen exposure is, in part, due to alterations in regulatory factors produced by thymic epithelial cells in response to a specific estrogen stimulus."

Fertil Steril 1983 Apr;39(4):485-489. **The effect of aqueous progesterone on operative adhesion Formation.** Maurer JH, Bonaventura LM "Progesterone (P) has been shown to have antiinflammatory and immunosuppressive properties. This study was designed to evaluate these effects on operative adhesion formation." Forty guinea pigs received standardized injuries to their uterine horns. Four groups were examined. Normal saline was used as an irrigant in the first, or control, group. Aqueous P (50 mg or 1 ml) was dripped over the injured site and instilled intraperitoneally in the second group. The third group received intramuscular aqueous P (3.3 mg/kg body weight) 1 day postoperatively, the day of surgery, and either 6 or 13 days postoperatively until reexploration. In the fourth group 1 ml of 32% dextran 70 (Hyskon) was administered in the same manner as aqueous P in the second group. The animals in all groups were reexplored 1 or 2 weeks after the initial surgical procedure, and the adhesions were scored. Adhesion formation was significantly reduced (P less than 0.001) in all treatment groups when compared with the control group."

Int J Immunopharmacol 2000 Nov;22(11):955-65. **Progesterone inhibits glucocorticoid-induced murine thymocyte apoptosis.** McMurray RW, Wilson JG, Bigler L, Xiang L, Lagoo A. "Sex and sex hormones modulate immune development and responses. A primary target of their effects is the structure and cellularity of the thymus; therefore, we examined the effects of sex and sex steroids on thymocyte apoptosis." **"Both estrogen and testosterone increased in vitro thymocyte apoptosis. In contrast, progesterone not only inhibited spontaneous in vitro thymocyte apoptosis, but also prevented in vitro glucocorticoid-induced apoptosis. Progesterone administration also suppressed glucocorticoid-induced in vivo thymocyte apoptosis. These results suggest that anti-apoptotic effects of progesterone may influence T cell development and subsequent immune responses."**

J Neuroimmunol 1997 May;75(1-2):1-8. **Inhibitory effect of pregnancy on stress-induced immunosuppression through corticotropin releasing hormone (CRH) and dopaminergic systems.** Nakamura H, Seto T, Nagase H, Yoshida M, Dan S, Ogino K "Decreases in splenic NKCA, corticotropin releasing hormone (CRH) in the hypothalamus, and increases in progesterone (P), beta-endorphin (beta EP), and dopamine (DA) metabolic ratios in the frontal cortex and nucleus accumbens produced by stress were recognized in the virgin rats, but not in the pregnant rats. Pregnancy reduced splenic NKCA in rats without stress, but elevated it in the rats exposed to stress with a duration of 180 min. These findings suggest inhibitory Effects of pregnancy on stress-induced immunosuppression and neuroendocrine changes, thereby promoting homeostasis in the neuroendocrine-immune system against stress. Such enhanced homeostasis associated with pregnancy seemed to be mediated by the activation of placental P and placental or pituitary beta EP in cooperation with mesocortical and mesolimbic DA systems and hypothalamic CRH."

Toxicology 2001 May 28;163(1):49-62. **Evidence for estradiol-induced apoptosis and dysregulated T cell maturation in the thymus.** Okasha SA, Ryu S, Do Y, McKallip RJ, Nagarkatti M, Nagarkatti PS. "The thymocytes from E2-treated mice when cultured in vitro for 24h, showed increased levels of apoptosis when compared to controls." "However, the total cellularity of all T cell subsets in the thymus was decreased following E2 treatment." "These data therefore confirmed that the thymocytes were indeed undergoing apoptosis following E2 treatment. Together, our studies suggest for the first time that estrogen may induce thymic atrophy by triggering apoptosis."

Am J Physiol Endocrinol Metab 2002 Nov;283(5):E909-16. **Endotoxemia reduces skeletal muscle protein synthesis in neonates.** Orellana RA, O'Connor PM, Nguyen HV, Bush JA, Suryawan A, Thivierge MC, Fiorotto ML, Davis TA. **"Protein synthesis in skeletal muscle is reduced by as much as 50% as early as 4 h after a septic challenge in adults."** "These findings suggest that, when substrate supply is maintained, skeletal muscle protein synthesis in neonates compared with adults is relatively resistant to the catabolic effects of sepsis."

Exp Neurol 1987 Mar;95(3):639-51. **Immunocomplexes in rat and rabbit spinal cord after injury.** Palladini G, Grossi M, Maleci A, Lauro GM, Guidetti B. "The possibility that, following a major lesion of the central nervous system, a humoral immune response could be evoked with formation of immune complexes "in situ" was investigated. For this purpose, an immunohistochemical study on rabbit and rat spinal cord at different times after surgical transection was carried out." "The results showed in the rabbit the absence of antibodies to neural antigens before surgical injury and its appearance within a few days after surgery. On the other hand, in the rat, even before the injury, we found antibodies to neural tissue which decreased in the first few hours after injury, and returned to control values during successive days." "The possible role of this immune response in the failure of axonal regeneration in mammalian spinal cord is briefly discussed."

FEBS Lett 1997 Apr 7;406(1-2):136-8. **Age-dependent decline in the cytochrome c oxidase activity in rat heart mitochondria: role of cardiolipin.** Paradies G, Ruggiero FM, Petrosillo G, Quagliariello E. "Cardiolipin is a major mitochondrial membrane lipid and plays a pivotal role in mitochondrial function. We have recently suggested a possible involvement of this phospholipid in the age-linked decline of cytochrome c oxidase activity in rat heart mitochondria [G. Paradies et al. (1993) Arch. Gerontol. Geriatr. 16, 263-272]." "We demonstrate that the lower cytochrome c oxidase activity in heart mitochondria from aged rats can be fully restored to the level of young control rats by exogenously added cardiolipin. No restoration was obtained with other phospholipids or with peroxidized cardiolipin. Our data support a key role for cardiolipin in the age-linked decline of rat heart mitochondrial cytochrome c oxidase activity."

Arch Biochem Biophys 1991 Feb 1;284(2):332-7. **Effect of aging on the activity of the phosphate carrier and on the lipid composition in rat liver mitochondria.** Paradies G, Ruggiero FM. "The effect of aging on the activity of the phosphate carrier and on the lipid composition in rat liver mitochondria has been investigated. It was found that the rate of phosphate transport in mitochondria from aged rats (28 months old) is significantly reduced (around 40%) compared to that obtained in mitochondria from young control rats (5 months old)." "The hepatic mitochondrial lipid composition is altered significantly in aged rats: the total cholesterol increases (31%), the phospholipids decrease (12%), and the cholesterol/phospholipid molar ratio increases (44%). Among the phospholipids cardiolipin shows the greatest alteration (30% decrease with age). Alterations were also found in the pattern of fatty acids. The age-related decrement in the activity of the phosphate carrier appears to be dependent on changes in the lipid domain surrounding the carrier protein molecule in the mitochondrial membrane."

J Exp Med 1978 Jun 1;147(6):1568-83. **Effect of castration and sex hormone treatment on survival, anti-nucleic acid antibodies, and glomerulonephritis in NZB/NZW F1 mice.** Roubinian JR, Talal N, Greenspan JS, Goodman JR, Siiteri PK."Mice receiving androgen showed improved survival, reduced anti-nucleic acid antibodies, or less evidence of glomerulonephritis as determined by light, immunofluorescent, and electron microscopy. By contrast, opposite effects were observed in castrated mice receiving estrogen. Intact male NZB/NZW F1 mice received androgen implants at 8 mo, an age when they develop an accelerated autoimmune disease associated with a decline in serum testosterone concentration. Such treated mice had improved survival and reduced concentrations of antibodies to DNA and to polyadenylic acid (Poly A)."

Ann N Y Acad Sci 1999 Jun 22;876:159-63. **Association between anticardiolipin antibody positivity and increased 17-beta-estradiol levels in premenopausal women with rheumatoid arthritis.** Seriolo B, Accardo S, Garnero A, Fasciolo D, Cutolo M

Clin Immunol Immunopathol 1983 Mar;26(3):361-9. **Effects of castration and sex hormones on immune clearance and autoimmune disease in MRL/Mp-lpr/lpr and MRL/Mp-+/+ mice.** Shear HL, Wofsy D, Talal N. "The clearance of erythrocytes sensitized with IgG was studied in MRL/Mp-lpr/lpr (MRL-lpr) and MRL/Mp-+/+ (MRL-+/+) mice, which spontaneously develop autoimmune disease." "Androgen treatment improved clearance in MRL-+/+ mice but not in MRL-lpr mice, even though autoantibody levels, renal function, and survival were improved. These results suggest that the beneficial effects of androgen on autoimmune disease are not due solely to improved clearance of immune complexes."

Kidney Int 1992 May;41(5):1245-53. **Essential fatty acid deficiency normalizes function and histology in rat nephrotoxic nephritis.** Takahashi K, Kato T, Schreiner GF, Ebert J, Badr KF "The central lipid abnormality in essential fatty acid deficiency (EFAD) is the lack of availability of arachidonic acid. To examine the role of total eicosanoid's biosyntheses in the pathology and pathophysiology of glomerulonephritis, EFAD was induced in weanling rats, which were then subjected to antiglomerular basement membrane antibody (NTS)-induced injury in adulthood." "Two hours post-NTS, and despite the occurrence of proteinuria in both EFAD and STD animals, glomerular dynamics were essentially normal in EFAD rats, whereas STD animals had reduced values for glomerular filtration rate (GFR) and renal plasma flow rate (RPF). At two weeks, severe histologic changes were observed in STD animals including mesangial and stalk hypercellularity, moderate sclerosis, and interstitial nephritis, coupled with heavy proteinuria and reduced GFR and RPF. In dramatic contrast, EFAD rats displayed totally normal glomerular structures and functions. In parallel, glomerular generation rates of prostaglandin E2 and thromboxane A2 were suppressed markedly in EFAD rats. **Thus, EFAD confers complete protection against the histopathologic and functional sequelae of immune-initiated injury in the glomerulus.** The data suggest that the initial wave of complement-induced neutrophil infiltration (with resultant proteinuria) is not sufficient to perpetuate injury into the more destructive chronic phases."

The New England Journal of Medicine Volume 326:513-518 February 20, 1992 Number 8. **Disappearance of thyrotropin-blocking antibodies and spontaneous recovery from hypothyroidism in autoimmune thyroiditis.** N Takasu, T Yamada, M Takasu, I Komiya, Y Nagasawa, T Asawa, T Shinoda, T Aizawa, and Y Koizumi. "Hypothyroidism may result from the production of antibodies that block the actions of thyrotropin." "Thyrotropin-blocking antibodies were detected in 9 percent of the patients with goitrous autoimmune thyroiditis and in 25 percent of those with atrophic autoimmune thyroiditis. Among the 21 patients studied serially while receiving levothyroxine, thyrotropin-blocking antibodies disappeared in 15 (group 1), 7 of whom had goiter initially, and persisted in 6 (group 2), none of whom had goiter initially. Levothyroxine therapy was subsequently discontinued in these 21 patients. Six of those in group 1 (four with goiter) remained euthyroid (mean follow-up after discontinuation of therapy, 2.1 years), and nine became hypothyroid again within 3 months. All six patients in group 2 remained hypothyroid." "Hypothyroidism in some patients with autoimmune thyroiditis may be due to thyrotropin-blocking antibodies. The production of thyrotropin-blocking antibodies may subside, producing remissions of hypothyroidism. Chronic autoimmune thyroiditis may therefore cause transient as well as permanent hypothyroidism."

J Rheumatol 1987 Jun;14 Suppl 13:21-5 **"Interleukin 2, T cell receptor and sex hormone studies in autoimmune mice."** Talal N, Dang H, Ahmed SA, Kraig E, Fischbach M. "Systemic lupus erythematosus (SLE) is a disease of immune dysregulation in which B cell hyperactivity and T cell deficiency are important characteristics. Sex factors also play a major role in the pathogenesis based on the physiologic effects of estrogen in promoting immunologic hyperactivity." "This aberrant T cell receptor might be explained by a defect in glycosylation. The administration of estrogen to pregnant mice late in gestation results in offspring with a permanently altered immune system. These mice develop features of autoimmunity similar to those that occur spontaneously in genetically susceptible autoimmune mice. This phenomenon may have etiopathological significance for familial SLE.

Ann N Y Acad Sci 1986;475:320-8 **Hormonal approaches to immunotherapy of autoimmune disease.** Talal N, Ahmed SA, Dauphinee M

Clin Rheum Dis 1982 Apr;8(1):23-8. **Sex hormones and modulation of immune response in SLE.** Talal N. Clearance of sensitized erythrocytes in NZB/NZW mice. Effects of castration and sex hormone treatment. Shear HL, Roubinian JR, Gil P, Talal N. The clearance of particulate immune complexes consisting of erythrocytes sensitized with IgG or complement was investigated in (NZB x NZW)F1 (B/W) mice. Treatment of castrated B/W mice with androgen or estrogen was able to modulate this clearance. Young (3-month-old) male and female B/W mice cleared IgG-sensitized mouse erythrocytes rapidly, whereas older males (13 months) and females (7 months) showed a marked impairment in their ability to clear these cells. In addition, erythrocytes sensitized **with complement in the absence of antibody were cleared within 5 min in**

young B/W mice. Older mice showed a greater and more rapid clearance rate of these cells. Castrated female B/W mice treated with androgen implants from three weeks of age showed improved clearance of IgG-sensitized erythrocytes at 7 months, whereas **estrogen-treated male mice showed delayed clearance. These results suggest an age-dependent defect** in the clearance of IgG-sensitized particles, perhaps due to diminished levels of serum complement and/or saturation of Fc receptors. In addition, there is an alteration in the clearance of complement-sensitized erythrocytes which may be related to changes in macrophage activity or enzyme inactivators of C3 and C4. The possible mechanisms responsible for the hormonal modulation of clearance are discussed in relation to the known ability of these hormones to influence autoimmune diseases.

Arthritis Rheum 1981 Aug; 24(8):1054-6 **Sex steroid hormones and systemic lupus erythematosus.** Talal N.

Med Cutan Ibero Lat Am 1980;8(1-3):15-21. **[Postovulation dermatitis (dermatitis caused by progesterone)]** Torras H, Ferrando J, Mallolas J. Postovulation Dermatitis is a frequent clinical picture although it is not well known. Clinically a polymorphous eruption appears between than 8 or 10 day before menses. The Authors report three cases in which an complete immunological investigation was performed. They conclude that there is no objective evidence of the autoimmune pathogeny of this picture in spite of the clinical relationship between the dermatitis and the ovulation. Therefore they suggest that diseases should be described as "Postovulation Dermatitis" instead "Autoimmune Progesterone Dermatitis".

J Endocrinol Invest 1993 Sep;16(8):619-24. **Hormonal pattern in women affected by rheumatoid arthritis.** Valentino R, Savastano S, Tommaselli AP, Riccio A, Mariniello P, Pronesti G, De Divitiis PM, Lombardi G. **"We have previously reported the presence of progesterone (P) deficiency in female patients with thyroid and ovarian autoimmune disease."** "In this context, the hormonal profile in 9 women with rheumatoid arthritis (RA) and in 9 age-matched ealthy women, were evaluated to verify the presence of a steroid hormone secretion impairment in a systemic autoimmune disease, further supporting our hypothesis of P deficiency involvement. P and androgen plasma levels, in the luteal phase, were significantly lower ($p < 0.05$ and 0.005, respectively) in RA patients than in the control group...." "Moreover, despite normal cortisol values, corticosterone (B) plasma levels were significantly higher in the RA patients ($p < 0.01$ and 0.05 in follicular and luteal phase, respectively). Therefore, our present data confirm the androgen deficiency in patients with a systemic autoimmune disease, such as RA and support the immunomodulator effect of P." "In conclusion, in addition to androgens, the immunomodulator role of P should also be taken into account in the pathogenesis of the systemic autoimmune disease."

Endocrinology 1994 Dec; 135(6): 2615-22. **"17 beta-estradiol, but not 5 alpha-dihydrotestosterone, augments antibodies to double-stranded deoxyribo- nucleic acid in nonautoimmune C57BL/6J mice."** Verthelyi D, Ahmed SA "In this study, we investigated the influence of gender and sex hormones on the development of antibodies to double-stranded DNA in nonautoimmune C57BL/6J mice." "In summary, our findings suggest that estrogen, but not dihydrotestosterone, promotes anti-dsDNA antibodies in normal mice."

Int Immunopharmacol 2001 Jun;1(6):983-93. **Sex hormones as immunomodulators in health and disease.** Verthelyi D. **"Studies in normal mice show that estrogen treatment induces polyclonal B cell activation with increased expression of autoantibodies characteristic of autoimmune diseases.** Several mechanisms appear to contribute to the break in tolerance and the increase in plasma cell activity including a reduction of the mass of the bone marrow and the thymus, the emergence of sites of extramedullary hematopoiesis and altered susceptibility of B cells to cell death. In addition, sex hormone levels in both humans and experimental models correlated with the activity of their cytokine-secreting cells indicating that sex hormones influence the cytokine milieu and suggesting that altered sex hormonal levels in autoimmune patients contribute to the skewed cytokine milieu characteristic of systemic lupus erythematosus (SLE)."

Cell Immunol 1998 Nov 1;189(2):125-34. **"Estrogen increases the number of plasma cells and enhances their autoantibody production in nonautoimmune C57BL/6 mice."** Verthelyi DI, Ahmed SA "In this study, by employing ELIspot, image cytometry, flow cytometry, cytology, and ELISA, we show that long-term exposure of normal mice to estrogen activates B cells to produce higher numbers of not only immunoglobulin-producing cells, but also autoantibody-producing cells. **Estrogen promoted a decrease in B220(+) splenic lymphocytes, but resulted in a 10-fold increase in plasma cells.** Further, the output of immunoglobulins including autoantibodies from individual plasma cells from estrogen-exposed mice was markedly increased, suggesting B cell hyperactivity. Importantly, our findings show that treatment of normal mice, solely with estrogen, can override B cell tolerance and promote autoreactive B cells in normal individuals."

Immunol Rev 1989 Aug;110:173-85. **Peripheral T cells select the B-cell repertoire in old mice.** Weksler ME, Russo C, Siskind GW. "These studies have shown that the alterations in the repertoire of antibody produced by old mice is not due to an intrinsic defect in the bone marrow or in the B-lymphocyte population arising from the bone marrow but rather to a selective downregulation by auto-anti-idiotypic antibody and idiotype-anti-idiotype interactions, shifting the idiotype distribution in the peripheral B-cell population." "The overall shift may be described as a decreased reactivity to foreign antigens and a complementary increase in reactivity with self antigens."

Proc Natl Acad Sci U S A 2002 May 28;99(11):7616-21. **The phytoestrogen genistein induces thymic and immune changes: a human health concern?** Yellayi S, Naaz A, Szewczykowski MA, Sato T, Woods JA, Chang J, Segre M, Allred CD, Helferich WG, Cooke PS. "Use of soy-based infant formulas and soy/isoflavone supplements has aroused concern because of potential estrogenic effects of the soy isoflavones genistein and daidzein. Here we show that s.c. genistein injections in ovariectomized adult mice produced **dose-responsive decreases in thymic weight of up to 80%.** Genistein's thymic effects occurred through both estrogen receptor (ER) and non-ER-mediated mechanisms, as the genistein effects on thymus were only partially blocked by the ER antagonist ICI 182,780. **Genistein decreased thymocyte numbers up to 86% and doubled apoptosis, indicating that the mechanism of the genistein effect on loss of thymocytes is caused in part by increased apoptosis." "Critically, dietary genistein at concentrations that produced serum genistein levels substantially less than those in soy-fed infants produced marked thymic atrophy.** These results raise the possibility that serum genistein concentrations found in soy-fed infants may be capable of producing thymic and immune abnormalities, as suggested by previous reports of immune impairments in soy-fed human infants."

Life Sci 2000 Mar 3;66(15):1451-9. **Supraphysiological level of estrogen exposure in vivo increases lymphoid cell death in mice.** Zajchowski S, Hoffman-Goetz L. "These results suggest that supraphysiological levels of estrogen in vivo induce damage in lymphoid cells; however, the impact of estrogen associated lymphoid tissue damage on specific immune functions remains to be determined."

Not for republication without written permission.

"In the last few months cardiac hormones (i.e. atrial natriuretic peptides) have been shown for the first time to decrease the size of infarcts after acute myocardial infarctions and to cure 80% of human pancreatic cancers and two-thirds of human breast cancers in athymic mice without any surgery. Even the human pancreatic cancers that were not cured had their volume decreased to less than 10% with each of four cardiac hormones and with vessel dilator to less than 2% compared to untreated animals. None of the treated human pancreatic cancer animals died of cancer – they lived a normal lifespan and died of old age."

"In the past year the mechanism of how cardiac hormones cure cancer(s) has been largely elucidated in cancer cells: They target the RAS/RAF-MEK 1/2-ERK 1/2 kinase cascade by inhibiting up to 98% of the activation (phosphorylation) of both MEK 1/2 and ERK 1/2 and block completely the stimulation of ERK by mitogens such as epideral growth factor resulting in decreased DNA synthesis within the nucleus of the cancer cell.

Cardiac hormones (i.e. atrial natriuretic peptides) consist of a family of peptides which are synthesized and then stored as three different prohormones, i.e., 126 amino acid (a.a.) atrial natriuretic peptide (ANP), 108 a.a. brain natriuretic peptide (BNP) and 103 a.a. C-natriuretic peptide (CNP) prohormones. Within the 126 a.a. ANP prohormone are four peptide hormones i.e. ANP, long acting natriuretic peptide (LANP), vessel dilator, and kaliuretic peptide with blood pressure lowering, natriuretic, diuretic and/or kaliuretic (i.e., potassium excreting) properties."

David Vesely, 2008

Peptides, coherent adaptation, and some terminal diseases: *The roles of thyroid, progesterone, calcium, salt--issues of energy and inflammation; towards an organismic paradigm for medicine*

In the last 50 years, huge numbers of people have probably suffered needlessly and died prematurely because of a mistaken bio-medical ideology. Much of that ideology has been deliberately imposed by a corrupt drug industry, which effectively controls the regulatory agencies, major medical journals and texts, and the way the mass media treat scientific ideas.

Scientific reductionism fosters specialization, and specialization leaves the "big picture" susceptible to manipulation by those with financial and political power.

The practice of medicine is still based on mechanistic biological doctrines, but some of the coherent holistic approaches that disappeared after the second world war are being vindicated by recent research.

In treating heart disease, it's common to prescribe one drug to modify the heart's contractions, another drug to modify the kidneys' handling of water and sodium, another drug that modifies the tension of the blood vessels, and a drug to inhibit blood clotting. In treating cancer, drugs to kill tumor cells are often combined with drugs to treat the side effects of the toxic drugs, and other drugs to treat symptoms produced by the cancer. Each drug has its particular "indications," and the whole process seems to be logical and rational, as long as the doctor participates in the mechanistic culture that describes the organism and each drug's effect on the organism.

Epilepsy, diabetes, osteoporosis, depression, boils, arthritis, insomnia, etc., all have their special mechanisms and special drugs.

When a practicing physician is confronted by a patient who is trying to think about the problem coherently, in terms of things that were known in 1940 or that have been recently discovered, it's extremely unlikely that the physician will take the time, or have the mental flexibility, to consider the patient's perspective.

There is nothing in the present medical culture that would allow a physician to consider that a common substance such as progesterone, or thyroid, or calcium, or sugar, might be able to prevent or alleviate or cure some or all of the conditions mentioned above. But there are some clearly established facts that have the potential of radically changing medical culture.

The idea of cell renewal ("tissue streaming") with coordinated multiplication of stem cells and safe dissolution (apoptosis) and recycling of mature cells has now reached mainstream biology, despite some occasional lip-service to the "Hayflick limit," which submerged the idea of continuous tissue renewal for 40 years. The idea of tissue-specific regulators of cell division (e.g., W.S. Bullough's chalones) was incompatible with the Hayflick doctrine that mature cells were incapable of dividing, and with the cancer doctrine, that only genetic mutant cells were able to continue dividing beyond the Hayflick limit of 50 divisions. But now, there is great interest in studying the many specific and general factors that regulate stem cells, differentiation, and apoptosis in the mature animal.

Some of these basic regulatory systems that have been ignored for so long turn out to be processes that we have in common with all forms of life.

Every cell contains proteolytic enzymes that break down enzymes and other proteins as new proteins are made. These changes allow the cell to adapt to changes in its environment, such as different energy sources. During stress, these enzymes are activated so that new systems can be quickly formed to meet the stress. When the stress is so intense that the cell is unable to adapt, enzymes of this sort break down the cell's structure, and the synthesis of new proteins stops, causing the cell to decompose in an orderly way. More intense and sudden stress can cause a less orderly kind of cellular death, but the proteolytic enzymes participate in that kind of dissolution too, though the peptide fragments produced are different.

Bacteria growing in colonies function in some ways like multicellular organisms, and the adaptive processes, including cell dissolution when the supply of food is depleted, allow the events in an individual cell to contribute to the regulation of the colony (Ben Jacob, et al., 2004). The peptide fragments that regulate bacterial colonies also influence the interactions between bacteria and more complex organisms, because stress-induced proteolysis is a universal feature of life, and very different organisms respond in similar ways to certain kinds of fragmented proteins.

The injury-induced alarm reactions that activate proteolytic enzymes in complex organisms typically release peptide fragments that are toxic to bacteria (possibly in a sort of "excitotoxicity"), and prevent their growth and invasion, while at the same time they stimulate wound healing and local cell division; if the local injury is serious enough, an amplified inflammatory reaction can involve the whole organism, its white blood cells and adaptive antibody production and hormonal and nervous reactions.

This kind of "innate immunity" is something we have in common with all forms of life. Coupled to the alarm/inflammatory system, there are more specific protective systems of regulatory peptides, that happen to be called "natriuretic peptides," although they do much more than regulating the kidneys' handling of sodium. They were first discovered in the atria of hearts, and so were called "atrial natriuretic peptide," ANP, but then peptides with similar structure and effects were found in the brain, and called "brain natriuretic peptide," BNP, and the next type to be discovered was called CNP.

Very similar peptides occur in mollusks, insects, reptiles, plants, and mammals, apparently in all multicellular organisms, and their functions in those organisms haven't been clarified, but their

universality has stimulated interest in exploring their multiple functions.

Many immunologists think of "innate immunity" as a primitive system that serves to activate the "higher" "adaptive immune system" of vertebrates. A major difference between these two systems is supposed to be the absence of memory in the innate system. In the 1950s, experimenters applied a little copper sulfate to the leaf of a plant, in a concentration just high enough to injure the tissue it touched. Then several days later, application of a highly diluted solution of the same chemical was found to cause an intense reaction and injury. The plant's "primitive" immune system demonstrated memory. "Stress memory" in plants is now more widely recognized (Goh, et al., 2003). Recent evidence (Bouché, et al., 2003; Baluška, et al., 2004; Bais, et al., 2004; Wipf, et al., 2002) supports J. C. Bose's early work showing nerve-like functions in plants.

In 1908, Ilya Mechnikov (also written Elie Metchnikoff) and Paul Ehrlich shared the Nobel prize for physiology or medicine, for their work on immunity.

Ehrlich is considered a pioneer in chemotherapy. His early work using synthetic dyes to stain bacteria and blood cells led him to the idea of a "magic bullet," in which a toxic substance (such as certain of the dyes that were being produced by the German chemical industry) would selectively kill a particular pathogen. His ideas led eventually to the current theory of using monoclonal antibodies as "magic bullets" to kill cancer cells.

Mechnikov was investigating embryology, trying to understand the principles by which an animal develops, when he realized that nutrition, especially the process of intracellular digestion of proteins, was a guiding force in the development of the organism, and later, considering the process of phagocytosis, he saw that this same principle was centrally involved in the organism's resistance to injury and infection. From seeing the place of cellular digestion and nutrition in the growth and survival of the organism, he extended his studies to the problem of the factors that influence the organism's resistance, for example why poor people are especially susceptible to infectious disease, and how toxins absorbed from the intestine weaken resistance to infections, and contribute to aging.

Acquired immunity, existing after recovering from an infection or being vaccinated, was well known to Mechnikov (he worked with Pasteur, for example), but he didn't make the extreme distinction between innate and adaptive immunity that is now often made.

For Mechnikov, the movement of cells from connective tissues into the blood, and from the blood into the endothelial and connective tissues, destroying harmful extraneous material or cells that were no longer useful, was an integral physiological process, influenced by the nervous system, to form and sustain the organism.

Although some of his contemporaries saw cellular immunity as a sort of mechanical and autonomous system (and some denounced him as a "vitalist" because of the intelligence he saw in cellular behavior), Mechnikov insisted that the processes of immunity were integral organismic processes, in which the nervous system had an essential role. Over the years, there have been many demonstrations of the brain's importance in the inflammatory process, but even the most recent studies that have found that "neuropeptides" appear to function as part of the "innate immune system" haven't achieved the comprehensive view of the organism that Mechnikov had.

Contemporary immunology and medicine see the immune system largely as Ehrlich saw it, as a specialized killing system. Like Ehrlich, few medical immunologists are interested in the similarities between plants and animals, because they see the human immune system as a unique thing evolved to more effectively destroy things which are "not-self."

The alternative view, that has grown out of Mechnikov's work, sees that the adaptiveness of plants and invertebrate animals gives us an essential perspective on our own biology. Growth, regeneration, stem cells, learning, and aging, have to be taken into account when thinking about infections, vaccinations, and the "autoimmune" diseases. We, humans and vertebrates generally, have a very intense energy metabolism that requires a powerful circulatory system that

supports a complex nervous system, but the similarities of the immune systems of the different phyla are in some ways more important than the differences. Learning or imprinting is something that can occur in any kind of cell, and the importance of the "simple" regulatory peptides of the innate immune system is now starting to be recognized in medicine.

All of our tissues, when damaged, can produce inflammation, stimulate growth, and signal to the rest of the organism that something is wrong. All, or most, of our tissues are also able to produce substances, the "natriuretic peptides," that restore stability, by reducing inflammation, inhibiting abnormal growth, increasing phagocytosis, and balancing energetic and synthetic metabolism and structural processes, including cellular differentiation, throughout the body.

The existence of these peptides in the other multicellular organisms, and the discovery that they act on pathogens (Krause, et al. 2001) as well as on the consequences of injury, suggests that they can be considered as part of the "immune system," but that recognition needn't detract from their roles in developmental, reproductive, and other basic biological processes. In the tradition of Mechnikov, it would be better to describe them as "morphostatic peptides," referring to Jamie Cunliffe's view of immunity, or "morphogenic peptides," to acknowledge that development never stops.

Cells that were once thought to cause autoimmune destruction are now known to be involved in repair and regeneration (Hofstetter, et al., 2003). Antibodies, rather than being just germ-killing proteins, or destructive autoantibodies, have many other functions, including the regulation of inflammation and regeneration (del Barco, et al., 2008; Bieber, et al., 2001; Schwartz, 2000). Phagocytes, besides eliminating foreign matter and exhausted cells, are considered to be "antigen presenting" cells that guide the adaptive immune system, but they also have an important role in guiding regeneration and differentiation of stem cells.

L.V. Polezhaev showed that processes similar to embryonic induction, guided by phagocytes, are involved in the organism's responses to damaged tissues. For example, when a piece of killed muscle tissue was enclosed in a porous capsule that permits molecules, but no cells, to diffuse through it, and implanted subcutaneously, it had no inductive effect on surrounding cells. But when the pores of the capsule allowed cells to enter, skeletal muscle formed where the dead tissue had been, and tissue resembling heart muscle formed outside the capsule. Phagocytosis had been essential for the induction to occur. The ingested material guided the differentiation of the surrounding cells.

The phagocytosis function isn't limited to the blood cells commonly called phagocytes; even nerve cells can ingest particles and fragments of damaged tissues. Polezhaev believed that fats were an inmportant factor in stimulating regeneration, and recent research shows that saturated fats and unsaturated fats have very different effects on the antigen presenting cells (Shaikh, et al., 2008). The innate immune system is probably impaired as a result of the cumulative toxicity of the polyunsaturated fats, contributing to the problems of aging.

Unsaturated fatty acids inhibit phagocytosis (Guimaraes, et al., 1991, 1992; Costa Rosa, et al., 1996; Virella, et al., 1989; Akamatsu, et al., 1990), and accumulate with aging. Phagocytosis decreases with aging, while other immune functions may increase. The age pigment, lipofuscin, consisting largely of oxidized polyunsaturated fats, impairs the phagocytic function even before it becomes grossly visible. The highly oxidizable n-3 polyunsaturated fats (Virella, et al., 1989) appear to be the most harmful to immunity against infections such as tuberculosis (Paul, et al., 1997).

ANP activates the phagocytic processes, while inhibiting inflammation (Borán, et al. 2008; Vollmar, et al., 1997).

The use of one of these nontoxic natriuretic peptides (BNP) as a drug for treating heart failure has possibly been helpful (Mohammed, et al., 2008), and now others have been discovered to be very active against cancer (Vesely, et al., 2006, 2008), but it shouldn't be necessary to wait for their availability as drugs, since their secretion can be induced by ordinary physiological means. Mechnikov and his contemporaries concentrated

mainly on trying to reduce the absorption of bacterial toxins from the intestine to preserve or restore the basic defensive and restorative processes, but in the last century new approaches have become possible.

Since these peptides were called "natriuretic" because of their effects on salt and water regulation, it seems reasonable to consider them in situations in which there are problems with the regulation of water and salt. Premenstrual syndrome, preeclampsia or pregnancy hypertension, congestive heart failure, brain swelling and seizures all involve disturbances of salt and water regulation, but the mechanical medical tradition has almost always substituted beliefs for facts.

Because of beliefs about cell physiology, most medical publications have argued for sodium restriction in those situations, but the evidence is clear that **inadequate salt retention** is usually their outstanding pathological feature.

Progesterone has been an effective treatment in all of those conditions, and it increases the ability of the kidneys to retain sodium. Progesterone increases ANP, and together they prevent sodium loss. (Because of this, it would be better to think of ANP as an *anti*natriuretic, rather than a natriuretic, peptide.) Each of them helps to prevent excessive vascular permeability (leakiness), and to inhibit the secretion of the antidiuretic hormone (ADH, or vasopressin) from the pituitary. ADH causes sodium loss, water retention, vascular leakiness, and constriction of arterioles, increasing blood pressure while decreasing the delivery of oxygen to the tissues, and increasing the tendency of blood to clot inappropriately.

Drugs to antagonize ADH are available, and are sometimes used to treat heart failure; these drugs help to **increase** sodium retention. Aldosterone antagonists (synthetic variations of progesterone) are also used to treat heart failure; they cause sodium to **decrease.** Progesterone, and the ANP it stimulates, would inhibit both ADH and aldosterone, regulating sodium and blood pressure and improving kidney function, while (like digitalis) progesterone strengthens the heart's contraction. The reason progesterone isn't used seems to be that no drug company promotes its use.

Estrogen is often recommended to "protect the heart," and even to treat heart failure, but it lowers ANP, increases ADH/vasopressin, causes water retention and sodium loss, vascular leakiness, and (like aldosterone) weakens the heart's contraction. Part of estrogen's action on capillaries results from increasing the vascular permeability factor (VPF), which is now called vascular endothelial growth factor (VEGF). This growth factor contributes to degenerative problems including diabetes, glaucoma, arthritis, atherosclerosis, and cancer, and blocking it can cause cancers to regress. ANP blocks the production and vascular action of VEGF (Pedram, et al., 2006). Both ANP and BNP protect against excessive permeability (Klinger, et al., 2006).

Thyroid hormone, like progesterone, also increases ANP, and, probably acting through increased carbon dioxide, is essential for regulating sodium and water. Hypertonic sodium chloride and increased carbon dioxide, in themselves, increase the formation of ANP. Caffeine is another substance which inhibits VEGF, while increasing ANP.

When an imbalance of these hormones allows too much sodium to be lost, and too much water to be retained, the phagocytic cells swell, and their autophagic and phagocytic activity is impaired, making the organism more susceptible to infection. Simply correcting the osmotic balance by supplementing salt can improve immune function (Junger, et al., 1994), as it stimulates respiratory metabolism, and increases carbon dioxide and body temperature. Increased carbon dioxide promotes tissue remodeling, lowers stress, and increases the synthesis of ANP (Kukacka, et al., 2007).

ANP protects against stress-induced excitatory effects of calcium (Green, et al., 2007; *Kuribayashi*, et al., 2006; Tian and Yang, 2006; Yoshioka, et al., 2000; Wang, et al., 1993).

Intracellular calcium overload is an essential feature of heart failure and hypertrophy (Malyshev Ilu, Meerson, 1990). Both vitamin D and vitamin K require carbon dioxide for disposing of calcium properly, preventing its toxicity. When carbon dioxide is inadequate, for example from simple hyperventilation or from hypothyroidism, calcium

is allowed to enter cells, causing inappropriate excitation, sometimes followed by calcification.

Keeping an optimal level of carbon dioxide (for example, when adapted to high altitude) causes calcium to be controlled (Arkhipenko, et al., 1992), resulting in lowered parathyroid hormone (PTH), an effect similar to supplementing with calcium, vitamin D, and vitamin K. (E.g., Nicolaidou, et al, 2006.) The contribution of PTH to inflammation and degeneration is just being acknowledged (e.g., Kuwabara, 2008). It suppresses phagocytosis (Esposito, et al., 1988; Smogorzewski, et al., 2001), probably by causing calcium overload, but in other situations it stimulates proliferation of lymphocytes and T cells (Klinger, et al., 1990; Adachi, et al., 1990).

The thyroid hormone, producing carbon dioxide, helps to sustain the level of ionized calcium (Lindblom, et al., 2001). In a vitamin D deficiency, or a calcium deficiency, the parathyroid hormone increases, and this hormone can contribute to many inflammatory and degenerative processes, including heart failure (Smogorzewski, 1995; Halapas, et al., 2006; Sugimoto, et al., 2008) and cardiac hypertrophy (Liu, et al., 2008). ANP and PTH have opposite effects on cellular calcium handling, and increasing the oral intake of calcium increases ANP (Halabe, et al., 1990), but lowers PTH.

Consuming enough calcium and vitamin D to keep the parathyroid hormone suppressed (and to support ANP) is important to protect against the degenerative conditions.

In organisms with a lower rate of metabolism, the regulatory substances are more closely associated with the organisms' structure, but in homeothermic animals with a high rate of metabolism, nerves and circulating hormones serve to reinforce the basic processes of immunity, allowing the whole organism to adapt coherently to sudden changes in its situation. These hormonal and nervous systems have "polarities" that are analogous to those of the innate peptide system, i.e., one side to defend and alarm and promote growth, another side to restore coherence and functions. The defensins are balanced by the "natriuretic peptides," while estrogen, VEGF, and ADH are balanced by progesterone and thyroid, and by the osmolarity, carbon dioxide, and heat that they sustain. The antimicrobials accelerate healing, but they also stimulate tumor growth, when they aren't balanced by the opposing systems.

Mechnikov was right in seeing bacterial toxins from the intestine as a cause of aging, and he was on the right track in trying to introduce a more beneficial bacterial ecology into the intestine by using sour milk. The lactobacilli do have some protective effects, but the lactic acid that they produce turns out to function as an alarm signal, which accelerates the same aging processes that the other bacterial endotoxins produce.

When these simple physical and chemical factors are well balanced, metabolism renews the structure of the organism, directing the differentiation of new cells and adjusting the composition of the intercellular substance, according to the type of stress the organism is experiencing.

Mechnikov's emphasis on the developmental, formative nature of the immune system, combining embryology and nutritional physiology with immunity, created the foundation for the understanding of regeneration and stem cell functions. Wandering cells can become structural parts of the fixed tissues and organs (Rohde, et al., 2007), or they can remove debris and call for more phagocytic cells, or they can signal for replacement stem cells and guide their differentiation.

Local-systemic interactions, in which local events cause systemic changes, and systemic events cause local changes, have been neglected and misinterpreted, especially where the "immune system" is concerned.

The recent renewal of interest in inflammation as a basic cause of chronic and degenerative disease, is a first step toward an integral therapeutic system, even though the systemic restorative processes are still being neglected.

Bacterial endotoxins are probably the central problem, but polyunsaturated fats, heavy metals, and extraneous hormones interact with them, extending their toxic actions.

Reducing the toxic factors, relative to the restorative factors, should be the aim, rather than looking for another drug.

When even a natural, endogenous substance is used as "a drug," the way it is conceptualized and

named is likely to reinforce the mechanical models of the organism, and those models are always inadequate. If we see health problems as events in an organism's adaptation to a problematic environment, the focus is shifted to the defects in the environment that might be remedied.

Resveratrol, rate of living, CO2, and aging

A year ago GlaxoSmithKline bought Sirtris, a company focusing on the biological effects of resveratrol, for $720,000,000. Harvard Medical School's website, and broadcasts by Barbara Walters and Morley Safer have publicized resveratrol as a longevity-increasing drug, and millions of people are spending large amounts of money for resveratrol capsules.

The main claim being made about resveratrol is that it can mimic the anti-aging effects of calorie restriction, without having to restrict food consumption. This involves silencing genes, blocking their production of RNA and protein.

The mass media and some medical journals aren't giving a balanced description of the biological effects of resveratrol, but many biologists are being influenced too, by the same simple arguments that the television reporters summarized. The academic biology culture, the medical culture, and the basic American culture itself, are all permeated by the idea of genetic determinism, so when a DNA molecule in yeast is identified as the "anti-aging gene," and a molecule is found that activates it, that molecule, or something similar, seems to them clearly to be an anti-aging drug.

Part of the cultural framework that makes it easy to sell that idea is the old "rate of living" theory of aging, the idea that we have only so many heartbeats in a lifetime, that we can use only so many calories and so much oxygen in a lifetime, and that organisms with a low metabolic rate therefore live longer than those with a high metabolic rate. The rate of living theory is closely related to the "wear and tear" theory of aging, that our bodies are (except for our germ cells) made up of "post-mitotic cells," unable to continue dividing once growth is complete, and so must die when those cells are "worn out." By the middle of the 20th century, those ideas had been disproved in many ways, but in the 1960s Leonard Hayflick renewed for a time the doctrine of aging as the wearing out of unrenewable cells, with his doctrine that somatic cells (non-germ cells) have an absolute limit of 50 replications. Producing cloned animals from somatic cells, and the subsequent excitement about stem cells, made that theory obsolete (again).

The "longevity gene," named Sir2 in yeasts, worms, and flies (its equivalent in mammals is called SirT1), is activated by restricting calories, and caloric restriction is known to extend lifespan (though the restriction of certain nutrients can similarly increase longevity, without restricting calories). Both semi-starvation and increased activity of the Sir2 gene can prevent obesity, and obesity has some harmful effects. The promoters of the theory suggest that a resveratrol-like drug will be able to prevent obesity and cure type-2 diabetes. They are also suggesting that it could slow aging and increase longevity.

Talking about the "aging" of a single-celled organism such as yeast, and drawing conclusions about the aging of multicellular organisms and humans, from events in the life of yeast, is meaningful only to people who subscribe to the Hayflick doctrine, and who deny the reality of stem cells in mammals and other complex organisms. They are actually talking about the "fertility," the reproductive growth capacity, of the yeasts. The study of yeast metabolism and growth developed mostly in relation to the needs of the wine and beer industries, and that has biased ideas about the ways yeast adapts to changing ecosystems. Yeasts adapt their reproductive strategy to the perceived adequacy of their environment. An individual yeast cell coordinates its physiology with the surrounding cells, in ways

analogous to the ways individual cells in an animal participate in the coherence of the organism.

As in higher organisms, stress can accelerate the reproductive process in yeast. In animals, stress can cause precocious puberty, as if they were being exposed to an excess of estrogen. Resveratrol is a defensive fungicidal antibiotic, or phytoalexin, so it's reasonable that it would be perceived as a stressor by yeast. It is also a phytoestrogen, and for many years yeasts have been known to be responsive to estrogenic substances. To the brewing industry, these effects of phytoestrogens are known to influence the biomass, but when the rate of growth is considered to represent aging, then increased biomass is equivalent to increased longevity.

Anyone familiar with the last 40 years of yeast research would presumably know that phenolic phytoalexins are estrogenic, and that the growth of yeast is influenced by estrogenic substances, and also that estrogenic substances such as resveratrol could be very dangerous if consumed in exaggeratedly large amounts.

Resveratrol is a stilbene, similar in structure to diethylstilbestrol, DES, the famously toxic-carcinogenic pharmaceutical. Estrogens affect all of the systems affected by resveratrol, and for 67 years, the estrogen industry has been telling the public that whatever estrogen does is beneficial---more than 200 medical conditions have been benefited by estrogen treatment, according to the medical literature/pharmaceutical advertising.

Many people have been asserting that the reason calorie restriction can extend life is that it activates "the antiaging gene, Sir2." A recent publication (Carrano, et al., 2009) from the Salk institute proposes that two other genes are responsible for calorie-restriction longevity in the roundworm, C. elegans.

But restricting calories has a multitude of effects--Sir2 is only one of hundreds of genes that function differently in hunger-stressed animals. Calorie restriction is stressful, but the nature of that stress and the response to it depends on the whole situation, just as in any other challenging situation.

One problem with the Sirtris scheme is that increased Sir2 activity shortens the actual chronological lifespan of non-dividing yeast (Kennedy, et al., 2005; Fabrizio, et al., 2005). In animals, increasing the activity of SirT1 might contribute to the development of cancer (Liu, et al., 2009). It might also be involved in Alzheimer's disease, and the replacement of nerve cells in the brain with astrocytes or other glial cells. Gliosis can occur in normal aging, but inflammation can produce extreme degrees of fibrosis of the brain or spongy encephalopathy. Estrogens also have this effect of accelerating stem cell production of glial cells.

In a recent study, to determine whether resveratrol would slow the heart rate and lower the body temperature in mice (as expected according to the rate of aging doctrine), those metabolic indicators were depressed by resveratrol for one day, but then returned to normal. However, the endurance of the mice on a treadmill was reduced by the resveratrol treatment (Mayers, et al., 2009).

Going beyond the Sir2 gene-based argument, many researchers have examined resveratrol's effects on various other genes. Too often, it seems that the authors reason that whatever resveratrol does to those genes must be good for the organism. These arguments seem to be following the reasoning that has been systematically used to promote estrogen and polyunsaturated fats.

If we consider the effects of resveratrol in the context of the well established facts about the metabolic processes associated with long life, we will notice many things that should lead to skepticism about the claims being made by the advertisers.

A little stress can make an organism more resistant to subsequent stresses. However, resveratrol fails to extend the lifespan of normal mice, being effective only in a strain of mice that becomes abnormally fat on a normal diet.

About 40 years ago, when people first began promoting fish oil as a longevity factor, Alex Comfort watched the rats that were being given the fish oil in their food. The food smelled bad, and the rats ate it only when they were very hungry, so they ate less and were leaner than the animals that were getting the standard diet. Their increased longevity was the result of avoiding obesity.

In a long-term study at NIH, rhesus monkeys are being studied to learn whether calorie restriction extends the lifespan of primates, as it does certain (genetically fat) rodents. The monkeys are kept in small cages. Confinement causes severe stress. Rats that are allowed to bite something while restrained suffer less physical stress, fewer ulcers, and are more able to maintain normal body temperature. Restraint normally lowers body temperature, lowering thyroid and increasing cortisol.

Eating in response to stress ameliorates some of the hormonal changes, but the monkeys that are permitted to eat as much as they want during their life of confinement have become very obese. They look much less agitated than the low calorie monkeys, and their body temperatures are higher.

The rate-of-living doctrine causes the researchers to reason that the low-calorie diet is slowing the rate of aging by lowering their body temperature. However, their metabolic rate, per gram of non-fat tissue, hasn't decreased.

An important difference that has been observed is that the chromosomes of the calorie deprived monkeys have more defects.

Nitric oxide, which is promoted by resveratrol, according to numerous publications (Klinge, et al., 2008; Gresele, et al. 2008; Gan, et al., 2009), and estrogens (acting partly through nitric oxide), including some phytoestrogens, cause chromosomal damage (Banerjee, et al., 1994; Kulling, et al., 1999) which contributes to cancer and possibly to birth defects. Nitric oxide has been proposed to be a major factor in causing the degenerative diseases of aging.

If these monkey experiments have any relevance to human biology, it is to demonstrate that prolonged torture by confinement and food restriction causes bodily damage, in the form of chromosomal abnormalities. But unless the next generation of monkeys is examined for birth defects and other problems, the full meaning of the experiment won't be apparent.

In some of the publications claiming that resveratrol increases lifespan, it was reported that niacinamide had the opposite effect, suppressing Sir2, the longevity gene, and shortening the organism's lifespan. To put their claims into context, it's helpful to look at a variety of experiments involving treatment with niacinamide.

It protects nerves, vascular cells, insulin-producing cells in the pancreas, and a variety of other types of cell from cell death produced by lack of oxygen, excitotoxicity, endotoxin, and a variety of stressors and toxins. (Niacinamide acts in many ways as a negation of resveratrol; for example, resveratrol interferes with the ability of the beta cells to secrete insulin [Szkudelski, 2007]).

Niacinamide protects mitochondrial respiration from many of the age-related factors that can damage mitochondria and decrease energy production. Lipopolysaccharide, the bacterial endotoxin, increases the production of the free radical nitric oxide, leading to the secretion of inflammatory mediators and the suppression of energy production by the mitochondria. These effects are blocked by niacinamide (Fukuzawa, et al., 1997). Calorie restriction also protects mitochondrial respiration, in yeasts (Lin, et al., 2002) and rats (Broderick, et al., 2002)

The "replicative lifespan" of human cells in vitro is extended by treatment with niacinamide (Kang, et al., 2006).

In an experiment with human keratinocytes *in vitro,* resveratrol had the opposite effect, reducing their ability to divide (Blander, et al., 2009). By the definitions of "aging" used by the advocates of the rate-of-living theory, this experiment suggests that resveratrol causes premature aging. Estrogen has a similar effect on keratinocytes. Resveratrol, nitric oxide, and estrogen, unlike niacinamide, suppress mitochondrial respiration. Resveratrol inhibits the formation of progesterone (Chen, et al., 2007), which is synthesized in mitochondria.

The NIH researchers reported that the food deprived monkeys (contrary to their expectation) didn't have a lower rate of metabolism, but many experiments done with a variety of very different animals through much of the last century found that a ***higher*** metabolic rate corresponded to increased longevity. Within a given species of bird or mammal, the higher rate of metabolism is often associated with a higher body temperature, and a long life span.

But when different types of animal of very different sizes are compared, smaller animals may have a higher rate of metabolism, but a shorter lifespan, than a larger animal, as in the case of mice and elephants. This example was used recently by an endocrinologist, Martin Surks, to argue against treating "subclinical hypothyroidism." He suggests that hypothyroid people, who have a lower rate of metabolism than euthyroid people, are likely to live longer, because their metabolism is analogous to the slow metabolism of elephants, rather than the fast metabolism of mice.

Comparing animals of different species, such as birds, monkeys, and rodents, of similar sizes, those with the highest metabolic rate are likely to have the longest average and maximum lifespans.

The smaller an organism is, the more easily it loses heat to the environment. Most of a mouse's metabolic energy is spent simply maintaining its body temperature. Large animals have less surface area in proportion to their mass, so they spend relatively little energy in temperature regulation.

One of the ideas deeply associated with the rate-of-living theory of aging is that our metabolic energy is spent mainly for regulating the concentration of salts and other substances in cells, with a small amount used for secretion, movement, and--a relatively recent admission--for thought.

Gilbert Ling has demonstrated the falsity of the idea that "membrane pumps" regulate the concentratons of dissolved materials, and showed that the amount of energy needed to operate them constantly would be much greater than the metabolic capacity of any organism.

The fact that those "membrane-based" energy consuming processes don't exist leaves a lot of energy to be accounted for. One of the main energy-consuming activities of a cell is just being alive, that is, adapting, sensing, responding, anticipating, orienting itself to its environment. Except in very special circumstances, the substance of a cell is in constant motion, and the molecules are being consumed and reconstructed, in a process of continuous renewal. These intracellular streams of renewal of molecules and organelles are paralleled on the scale of tissues and organs by a process of renewal, in which new cells are born and unnecessary cells are dissolved.

Part of the "rate of living" relates to the rate of renewal of the organism. Another part relates to issues such as the loss of heat, that makes life shorter and harder for very small animals.

The end product of respiration is carbon dioxide, and it is an essential component of the life process. The ability to produce and retain enough carbon dioxide is as important for longevity as the ability to conserve enough heat to allow chemical reactions to occur as needed.

Carbon dioxide protects cells in many ways. By bonding to amino groups, it can inhibit the glycation of proteins during oxidative stress, and it can limit the formation of free radicals in the blood; inhibition of xanthine oxidase is one mechanism (Shibata, et al., 1998). It can reduce inflammation caused by endotoxin/LPS, by lowering the formation of tumor necrosis factor, IL-8 and other promoters of inflammation (Shimotakahara, et al., 2008). It protects mitochondria (Lavani, et al., 2007), maintaining (or even increasing) their ability to respire during stress.

The "replicative lifespan" of a cell can be shortened by factors like resveratrol or estrogen that interfere with mitochondrial production of carbon dioxide. Both of those chemicals cause skin cells, keratinocytes, to stop dividing, to take up calcium, and to begin producing the horny material keratin, that allows superficial skin cells to form an effective barrier. This process normally occurs as these cells differentiate from the basal (stem) cells and, by multiplying, move farther outward away from the underlying blood vessels that provide the nutrients that are oxidized to form carbon dioxide, and as they get farther from the blood supply, they get closer to the external air, which contains less than 1% as much CO2 as the blood. This normally causes their eventual hardening into the keratin cells, but when conditions are optimal, numerous layers of moist, translucent cells that give the skin the characteristic appearance of youth, will be retained between the basal cells and the condensed surface layers. (Wilke, et al., 1988)

In other types of tissue, a high level of carbon dioxide has a similar stabilizing effect on cells, preserving stem cells, limiting stress and preventing loss of function. In the lining of the mouth, where the oxygen tension is lower, and carbon

dioxide higher, the cells don't form as much keratin as the skin cells do. In the uterus, the lining cells would behave similarly, except that estrogen stimulates keratinization. A vitamin A deficiency mimics an estrogen excess, and can cause excessive keratinization of membrane cells.

Yeasts adapt their physiology and life cycle to their particular ecological situation. The cells within an animal behave analogously, but that is likely to be forgotten or denied, because of the culture of genetic determinism.

The cells in each organ and tissue of the body are arranged in ways that allow them to make their contribution to the function of the organism, while receiving oxygen, glucose, and regulatory substances in the blood, and maintaining and renewing themselves. Except for the skin, their situation amid other cells assures that they will live in a high concentration of carbon dioxide.

There are proteins (uncoupling proteins, UCP) that cause the mitochondria to increase their consumption of oxygen without increasing their synthesis of ATP. The synthesis of ATP is usually thought of as the main reason for the consumption of oxygen, so the UCP have been assumed to exist to increase heat production. The formation of carbon dioxide is usually thought of as just an unavoidable consequence. UCP proteins, however, exist in situations in which heat production doesn't seem appropriate (Borecký & Vercesi, 2005; Aguilera, et al., 2005; Gnanalingham, et al., 2005). For example, fasting or calorie restriction increases UCP, tending to cause tissues to consume energy more rapidly. Stress and hypoxia also can increase UCP, suggesting that these enzymes have protective functions.

Increasing the formation of carbon dioxide seems to me to be the essential function of the UCP. Thyroid hormone (T3) increases UCP, and UCP increases the formation of new mitochondria. Increased activity of the UCP is closely associated with increased lifespan. A decreased amount of T3 in tissues during aging corresponds to decreasing mitochondrial functon.

Increased CO2 inhibits the formation of lactate, decreases the lipolytic effect of adrenaline, and the lowered energy charge produced by the UCP would prevent the diversion of glucose into other uses.

According to the rate-of-living theory of aging, the "post-mitotic" organism ages and degenerates in proportion to the rate at which it metabolizes. Leonard Hayflick, to demonstrate that it is cell division, not the passage of time, that ages cells, put some cells in a freezer, while others, from the same batch, were kept in a warm incubator and allowed to go through their allotted number of divisions. When the warm, growing cells had approached 50 replications and began dying "of old age," the other cells were taken out of the freezer, and they were able to divide as well as they had before being frozen. The implication was that slowing metabolism was the only way to extend the lifespan.

These beliefs have allowed people to view the metabolism, the turnover of substance and cells, of a tissue such as bone, as indicating breakdown, weakening, and loss. For many years, it was impossible to show any beneficial effect of estrogen on the bones of experimental animals or people, but then it was discovered that it could slow the metabolism of the osteoclasts, reducing the rate of turnover in the bones. This was propagandistically effective.

The estrogen industry's funding greatly reinforced the rate-of-living theory of aging, and metabolic markers of bone turnover began to be used to measure the effects of treatment. Thyroid hormone (the active T3 hormone) increases the rate of turnover of all tissues, including bone, so by reference to the "bone protective effects of estrogen," the argument was made that thyroid supplementation should be reduced, to prevent osteoporosis (despite animal studies showing that T3 increases bone development). Since hypothyroidism usually involves increased thyroid stimulating hormone, TSH, the argument was extended by showing that TSH lowers bone turnover.

One factor involved in the increased production of TSH in hypothyroidism is that the low metabolic rate allows estrogen to accumulate, leading to increased serotonin production. Serotonin stimulates both TSH and prolactin. Serotonin and prolactin both happen to cause bone loss. They increase nitric oxide, which inhibits mitochondrial respiration. Serotonin increases a cytokine, osteoprotegerin, that inhibits osteoclasts, reducing bone turnover. However,

serotonin's other antimetabolic effects outweigh that effect, and it is a major factor in causing osteoporosis. The antimetabolic factors that slow the rate of living also slow the rate of renewal, and on balance lead to tissue atrophy, fibrosis, inflammation, and degeneration. Several decades after estrogen-induced prolactin might have been recognized as a cause of bone loss in aging, a few people are mentioning the mechanism in specific situations (Horner, 2009; Horner, et al., 2007).

With aging, metabolic activity and the turnover of biological substance decrease. Organelles such as mitochondria are renewed every day or two, much of the brain substance has a similarly fast rate of turnover, and other parts of the body are renewed more slowly. When conditions are optimal, the new structures are flawless, but under the wrong conditions, faulty repairs can accumulate, producing the degenerative problems of aging.

Our culture's understanding of biology has been shaped by a series of ideologies, and currently the drug industry is the main force shaping those ideologies, creating an attitude that's receptive to their products.

The huge marketing campaign for resveratrol will have direct effects on people's health, probably extending beyond the generation that uses it, but it is also polluting the culture by reinforcing the doctrine that torpor, slowing the life process, is beneficial.

Glucose and sucrose for diabetes

Diabetes has been known since ancient times as a wasting disease in which sugar was lost in the urine, but more recently the name has been used to describe the presence of more than the normal amount of glucose in the blood, even in the absence of glucose in the urine. Some of the medical ideas regarding the original form of the condition have been applied to the newer form.

Cultural "paradigms" or ideologies are so convenient that people often don't bother to doubt them, and they are sometimes so rigorously enforced that people learn to keep their doubts to themselves. Public concern about diabetes has been growing for decades, but despite the introduction of insulin and other drugs to treat it, and massive campaigns to "improve" eating habits, mortality from diabetes has been increasing during the last 100 years. Diabetes ("type 1") has been increasing even among children (Barat, et al., 2008).

A basic meaning of homeopathic medicine is the support of the organism's ability to heal itself; the essence of allopathy is that the physician fights "a disease" to cure the patient, e.g., by cutting out tumors or killing germs.

Confidence in the organism's essential rationality led the doctors with a homeopathic orientation to see a fever as part of a recuperative process, while their allopathic opponents sometimes saw fever as the essence of the sickness to be cured. Homeopaths concentrated on the nature of the patient; allopaths concentrated on a disease entity in itself, and were likely to ignore the patient's idiosyncrasies and preferences.

Diabetes was named for the excessive urination it causes, and for the sugar in the urine. It was called the sugar disease, and physicians were taught that sugar was the problem. Patients were ordered to avoid sweet foods, and in hospitals they were sometimes locked up to keep them from finding sweets. The practice was derived from ideology, not from any evidence that the treatment helped.

In 1857, M. Piorry in Paris and William Budd in Bristol, England, reasoned that if a patient was losing a pound of sugar every day in 10 liters of urine, and was losing weight very rapidly, and had an intense craving for sugar, it would be reasonable to replace some of the lost sugar, simply because the quick weight loss of diabetes invariably led to death. Keeping patients from eating what they craved seemed both cruel and futile.

After Budd's detailed reports of a woman's progressive recovery over a period of several weeks when he prescribed 8 ounces of sugar every day, along with a normal diet including beef and beef broth, a London physician, Thomas Williams, wrote sarcastically about Budd's metaphysical ideas, and reported his own trial of a diet that he described as similar to Budd's. But after two or three days he decided his patients were getting worse, and stopped the experiment.

Williams' publication was presented as a scientific refutation of Budd's deluded homeopathic ideas, but Budd hadn't explained his experiment as anything more than an attempt to slow the patient's death from wasting which was sure to be the result of losing so much sugar in the urine. The following year Budd described another patient, a young man who had become too weak to work and who was losing weight at an extreme rate. Budd's prescription included 8 ounces of white sugar and 4 ounces of honey every day, and again, instead of increasing the amount of glucose in the urine, the amount decreased quickly as the patient began eating almost as much sugar as was

being lost initially, and then as the loss of sugar in the urine decreased, the patient gained weight and recovered his strength.

Drs. Budd and Piorry described patients recovering from an incurable disease, and that has usually been enough to make the medical profession antagonistic. Even when a physician has himself diagnosed diabetes and told a patient that it would be necessary to inject insulin for the rest of his life, if that patient recovers by changing his diet, the physician will typically say that the diagnosis was wrong, because diabetes is incurable.

Twenty-five years ago, some rabbits were made diabetic with a poison that killed their insulin-secreting pancreatic beta-cells, and when some of them recovered from the diabetes after being given supplemental DHEA, it was found that their beta-cells had regenerated. The more recent interest in stem cells has led several research groups to acknowledge that in animals the insulin-producing cells are able to regenerate.

It is now conceivable that there will be an effort to understand the factors that damage the beta-cells, and the factors that allow them to regenerate. The observations of Budd and Piorry would be a good place to start such a reconsideration.

For many years, physicians have been taught that diabetes is either "genetic" or possibly caused by a viral infection, that might trigger an "autoimmune reaction," but the study of cellular respiration and energy metabolism and endocrinology has provided more convincing explanations. The antibodies that are found in the "autoimmune" conditions are evidence of tissue damage, but the damage may have been done by metabolic toxins, with the immune system's involvement being primarily the removal of defective cells.

In the 1940s, Bernardo Houssay found that coconut oil protected animals from poison-induced diabetes, while a lard-based diet failed to protect them. Later, glucose itself was found to protect the pancreatic beta-cells from poisons.

In 1963, P.J. Randle clearly described the inhibition of glucose oxidation by free fatty acids. Later, when lipid emulsions came into use for intravenous feeding in hospitals, it was found that they blocked glucose oxidation, lowered the metabolic rate, suppressed immunity, and increased lipid peroxidation and oxidative stress.

Estrogen and stress are both known to create some of the conditions of diabetes, while increasing fat oxidation and inhibiting glucose oxidation. Emotional stress, overwork, trauma, and infections have been known to initiate diabetes. Estrogen increases free fatty acids and decreases glycogen storage, and when birth control pills were becoming popular, some researchers warned that they might cause diabetes. But the food oil industry and the estrogen industry were satisfied with the medical doctrine that diabetes was caused by eating too much sugar.

If the essence of diabetes is the presence of too much sugar, then it seems reasonable to argue that it is the excess sugar that's responsible for the suffering and death associated with the disease, otherwise, how would the prohibition of sugar in the diet be justified? In fact, the argument is made (e.g., Muggeo, 1998) that it is the hyperglycemia that causes problems such as hypertension, kidney failure, heart failure, neuropathy, blindness, dementia, and gangrene.

As information about the many physiological and biochemical events associated with diabetes has accumulated, the basic doctrine that "sugar causes diabetes" has extended itself to whatever the topic of discussion is: "Glucose causes" the death of beta-cells, glucose causes blood vessels to become leaky, glucose causes cells to be unable to absorb glucose, glucose causes the formation of free radicals, glucose impairs immunity and wound healing, but causes inflammation while preventing the "respiratory burst" in which free radicals are produced by cells that cause inflammation, it disturbs enzyme functions, impairs nerve conduction and muscle strength, etc., and it is also addictive, causing people to irrationally seek the very material that is poisoning them.

Tens of thousands of publications describe the pathogenic effects of sugar. To prove their point, they grow cells in a culture dish, and find that when they are exposed to excess glucose, often 5 times the normal amount, they deteriorate. In the artificial conditions of cell culture, the oversupply of glucose causes lactic acid to accumulate,

leading to toxic effects. But in the organism, the hyperglycemia is compensating for a sensed deficiency of glucose, a need for more energy.

If diabetes means that cells can't absorb or metabolize glucose, then any cellular function that requires glucose will be impaired, despite the presence of glucose in the blood. It is the intracellular absence of glucose which is problematic, rather than its extracellular excess.

Neuroglycopenia (or neuroglucopenia) or intracellular glycopenia refers to the deficit of glucose in cells. When the brain senses a lack of glucose, nerves are activated to increase the amount of glucose in the blood, to correct the problem. As long as the brain senses the need for more glucose, the regulatory systems will make the adjustments to the blood glucose level.

The antagonism between fat and sugar that Randle described can involve the suppression of sugar oxidation when the concentration of fats in the bloodstream is increased by eating fatty food, or by releasing fats from the tissues by lipolysis, but it can also involve the suppression of fat oxidation by inhibiting the release of fatty acids from the tissues, when a sufficient amount of sugar is eaten.

When a normal person, or even a "type 2 diabetic," is given a large dose of sugar, there is a suppression of lipolysis, and the concentration of free fatty acids in the bloodstream decreases, though the suppression is weaker in the diabetic (Soriguer, et al., 2008). Insulin, released by the sugar, inhibits lipolysis, reducing the supply of fats to the respiring cells.

Free fatty acids suppress mitochondrial respiration (Kamikawa and Yamazaki, 1981), leading to increased glycolysis (producing lactic acid) to maintain cellular energy. The suppression of mitochondrial respiration increases the production of toxic free radicals, and the decreased carbon dioxide makes the proteins more susceptible to attack by free radicals. The lactate produced under the influence of excessive fat metabolism stimulates the release of endorphins, which are lipolytic, releasing more free fatty acids from the tissues. Acting through cytokines such as interleukin-6, lactate shifts the balance toward the catabolic hormones, leading to tissue wasting.

Lactic acid itself, and the longer chain fatty acids, inhibit the regulatory enzyme pyruvate dehydrogenase (which is activated by insulin), reducing the oxidative production of energy. Drugs to activate this enzyme are being studied by the pharmaceutical industry as treatments for diabetes and cancer (for example, DCA, dichloroacetate).

Oxidative damage of proteins is often described as glycation or glycosylation, but it really consists of many addition and crosslinking reactions, most often onto, or between, lysine groups. Carbon dioxide normally associates with lysine groups, so the destructive reactions are favored when carbon dioxide is displaced by lactic acid. The reactive fragments of polyunsaturated fatty acids are much more often the source of the protein-damaging radicals than the carbohydrates are.

The importance of the fats in causing type-2 diabetes is coming to be accepted, for example Li, et al., recently (2008) said "The cellular link between fatty acids and ROS (reactive oxygen species) is essentially the mitochondrion, a key organelle for the control of insulin secretion. Mitochondria are the main source of ROS and are also the primary target of oxidative attacks."

But much earlier (Wright, et al., 1988) it had been demonstrated that a deficiency of the "essential fatty acids" prevents toxin-induced diabetes and greatly increases resistance to inflammation (Lefkowith, et al., 1990). The lack of those so-called "essential fatty acids" also prevents autoimmune diabetes in a strain of diabetic mice (Benhamou, et al., 1995),

Suppressing fatty acid oxidation improves the contraction of the heart muscle and increases the efficiency of oxygen use (Chandler, et al., 2003). Various drugs are being considered for that purpose, but niacinamide is already being used to improve heart function, since it lowers the concentration of free fatty acids.

The antimetabolic and toxic effects of the polyunsaturated fatty acids can account for the "insulin resistance" that characterizes type-2 diabetes, but similar actions in the pancreatic beta-cells can impair or kill those cells, creating a deficiency of insulin, resembling type-1 diabetes.

The suppression of mitochondrial respiration causes increased free radical damage, and the presence of polyunsaturated fatty acids in the suppressed cell increases the rate of fat decomposition and production of toxins.

Increasing the rate of respiration by replacing the fats with glucose reduces the availability of electrons that can trigger lipid peroxidation and produce toxic free radicals, and the shift of fuel also increases the amount of carbon dioxide produced, which can protect the protein amino groups such as lysine from glycation and lipoxidation.

While it's clear that it is the excessive oxidation of fat that damages cells in the "diabetic" state in which cells aren't able to use glucose, it's important to look at some of the situations in which so many researchers are blaming problems on hyperglycemia.

Important problems in diabetes are slow wound healing, excessive permeability or leakiness of blood vessels which allows molecules such as albumin to be extravasated, and the impaired function and survival of pancreatic beta-cells.

During the healing of a wound in a diabetic individual, the local concentration of glucose decreases and then entirely disappears, as healing stops. Applying glucose and insulin topically to the wound, it heals quickly. The very old practice of treating deep wounds with honey or granulated sugar has been studied in controlled situations, including the treatment of diabetic ulcers, infected deep wounds following heart surgery, and wounds of lepers. The treatment eradicates bacterial infections better than some antiseptics, and accelerates healing without scarring, or with minimal scarring. The sugar regulates the communication between cells, and optimizes the synthesis of collagen and extracellular matrix.

An excess of insulin, causing hypoglycemia, can cause blood vessels, for example in the brain and kidneys, to become leaky, and this has been claimed to be an effect of insulin itself. However, the same leakiness can be produced by an analog of glucose that can't be metabolized, so that intracellular glycopenia is produced. The harmful effect that has been ascribed to excessive insulin can be prevented by maintaining an adequate supply of glucose (Uezu and Murakami, 1993), showing that it is the lack of glucose, rather than the excess insulin, that causes the vascular malfunction. Fructose also reduces the leakiness of blood vessels (Plante, et al., 2003). Many of the complications of diabetes are caused by increased vascular leakiness (Simard, et al., 2002).

Sugar can protect the beta-cells from the free fatty acids, apparently in the same ways that it protects the cells of blood vessels, restoring metabolic energy and preventing damage to the mitochondria. Glucose suppresses superoxide formation in beta-cells (Martens, et al., 2005) and apparently in other cells including brain cells. (Isaev, et al., 2008).

The beta-cell protecting effect of glucose is supported by bicarbonate and sodium. Sodium activates cells to produce carbon dioxide, allowing them to regulate calcium, preventing overstimulation and death. For a given amount of energy released, the oxidation of glucose produces more carbon dioxide and uses less oxygen than the oxidation of fatty acids.

The toxic excess of intracellular calcium that damages the insulin-secreting cells in the relative absence of carbon dioxide is analogous to the increased excitation of nerves and muscles that can be produced by hyperventilation.

In every type of tissue, it is the failure to oxidize glucose that produces oxidative stress and cellular damage. Even feeding enough sucrose to cause fat deposition in the liver can protect the liver from oxidative stress (Spolarics and Meyenhofer, 2000), possibly by mechanisms such as those involved in the treatment of alcoholic liver disease with saturated fats.

The active thyroid hormone, T3, protects the heart by supporting the oxidation of glucose (Liu, et al., 1998). The amount of T3 produced by the liver depends mainly on the amount of glucose available.

Animals that have been made diabetic with relatively low doses of the poison streptozotocin can recover functional beta-cells spontaneously, and the rate of recovery is higher in pregnant animals (Hartman, et al., 1989). Pregnancy stabilizes blood sugar at a higher level, and

progesterone favors the oxidation of glucose rather than fats.

A recent study suggests that recovery of the pancreas can be very fast. A little glucose was infused for 4 days into rats, keeping the blood glucose level normal, and the mass of beta-cells was found to have increased 2.5 times. Cell division wasn't increased, so apparently the additional glucose was preventing the death of beta-cells, or stimulating the conversion of another type of cell to become insulin-secreting beta-cells (Jetton, et al., 2008).

That study is very important in relation to stem cells in general, because it either means that glandular cells are turning over ("streaming") at a much higher rate than currently recognized in biology and medicine, or it means that (when blood sugar is adequate) stimulated cells are able to recruit neighboring cells to participate in their specialized function. Either way, it shows the great importance of environmental factors in regulating our anatomy and physiology.

"Diabetologists" don't regularly measure their patients' insulin, but they usually make the assumption that insulin is the main factor regulating blood sugar. In one study, it was found that the insulin molecule itself, immunoreactive insulin, accounted for only about 8% of the serum's insulin-like action. The authors of that study believed that potassium was the main other factor in the serum that promoted the disposition of glucose. Since potassium and glucose are both always present in the blood, their effects on each other have usually been ignored.

Cellular activation (by electrical, nervous, chemical, or mechanical stimulation) causes glucose to be absorbed and oxidized, even in the absence of insulin and in otherwise insulin-resistant individuals. I think this local interaction between the need for energy and the production of energy predominates in good health, with insulin and other hormones facilitating the process in times of stress. A variety of local tissue regulators, including GABA and glutamate, probably participate in these interactions, in the brain, endocrine glands, muscles, and other tissues, and are probably involved in the relaxing and analgesic actions of the sugars.

The GABA system (GABA is highly concentrated in the beta-cells) is involved in regulating blood sugar, inhibiting the release of glucagon when glucose isn't needed, and apparently allowing the beta cells to discriminate between amino acids and glucose (Gu, et al., 1993) and acting as a survival and growth factor for neighboring cells (Ligon, et al., 2007).

The damaged beta-cells lose the enzyme (glutamate dehydrogenase) that makes GABA, and their ratio of linoleic acid to saturated and monounsaturated fat increases, a change that corresponds to a decreased metabolism of glucose.

The free intracellular calcium that can become toxic is normally bound safely by well-energized mitochondria, and in the bloodstream it is kept safely complexed with carbon dioxide. The thyroid hormone, producing carbon dioxide, helps to sustain the level of ionized calcium (Lindblom, et al., 2001). In a vitamin D deficiency, or a calcium deficiency, the parathyroid hormone increases, and this hormone can contribute to many inflammatory and degenerative processes, including diabetes. Consuming enough calcium and vitamin D to keep the parathyroid hormone suppressed is important to protect against the degenerative conditions.

When animals were fed an otherwise balanced diet lacking vitamin D, with the addition of either 68% sucrose or 68% starch, the bones of those on the starch diet failed to develop normally, as would be expected with a vitamin D deficiency, and their serum calcium was low. However, the bones of those on the diet with sucrose developed properly, and didn't show evidence of being calcium deficient, though they weren't quite as heavy as those that also received an adequate amount of vitamin D (Artus, 1975). This study suggests that the famous dietetic emphasis on the "complex carbohydrates," i.e., starches, has made an important contribution to the prevalence of osteoporosis, as well as obesity and other degeneration conditions.

Both vitamin D and vitamin K, another important calcium-regulating nutrient, are now known to prevent diabetes. Both of these vitamins require carbon dioxide for disposing of calcium properly,

preventing its toxicity. When carbon dioxide is inadequate, for example from simple hyperventilation or from hypothyroidism, calcium is allowed to enter cells, causing inappropriate excitation, sometimes followed by calcification.

Keeping an optimal level of carbon dioxide (for example, when adapted to high altitude) causes calcium to be controlled, resulting in lowered parathyroid hormone, an effect similar to supplementing with calcium, vitamin D, and vitamin K. (E.g., Nicolaidou, et al, 2006.) Glycine, like carbon dioxide, protects proteins against oxidative damage (Lezcano, et al., 2006), so including gelatin (very rich in glycine) in the diet is probably protective.

The contribution of PTH to inflammation and degeneration is just being acknowledged (e.g., Kuwabara, 2008), but the mechanism undoubtedly involves the fact that it is lipolytic, increasing the concentration of free fatty acids that suppress metabolism and interfere with the use of glucose.

When we talk about increasing the metabolic rate, and the benefits it produces, we are comparing the rate of metabolism in the presence of thyroid, sugar, salt, and adequate protein to the "normal" diet, containing smaller amounts of those "stimulating" substances. It would be more accurate if we would speak of the suppressive nature of the habitual diet, in relation to the more optimal diet, which provides more energy for work and adaptation, while minimizing the toxic effects of free radicals.

Feeding animals a normal diet with the addition of Coca-Cola, or with a similar amount of sucrose, has been found to let them increase their calorie intake by 50% without increasing their weight gain (Bukowiecki, et al., 1983). Although plain sucrose can alleviate the metabolic suppression of an average diet, the effect of sugars in the diet is much more likely to be healthful in the long run when they are associated with an abundance of minerals, as in milk and fruit, which provide potassium and calcium and other protective nutrients.

Avoiding the starches such as cereals and beans, and using fruits as a major part of the diet helps to minimize the effects of the polyunsaturated fats.

Celiac disease or gluten sensitivity is associated with diabetes and hypothyroidism. There is a cross reactivity between the gluten protein molecule and an enzyme which is expressed under the influence of estrogen. This is another reason for simply avoiding cereal products.

Brewers' yeast has been used traditionally to correct diabetes, and its high content of niacin and other B vitamins and potassium might account for its beneficial effects. However, eating a large quantity of it is likely to cause gas, so some people prefer to extract the soluble nutrients with hot water. Yeast contains a considerable amount of estrogen, and the water extract probably leaves much of that in the insoluble starchy residue. Liver is another rich source of the B vitamins as well as the oily vitamins, but it can suppress thyroid function, so usually one meal a week is enough.

The supplements that most often help to correct diabetes-like conditions are niacinamide, thiamine, thyroid, and progesterone or pregnenolone. Vitamins D and K are clearly protective against developing diabetes, and their effects on many regulatory processes suggest that they would also help to correct existing hyperglycemia.

Drinking coffee seems to be very protective against developing diabetes. Its niacin and magnesium are clearly important, but it is also a rich source of antioxidants, and it helps to maintain normal thyroid and progesterone production. Chocolate is probably protective too, and it is a good source of magnesium and antioxidants.

A recent study (Xia, et al., 2008) showed that inhibition of cholesterol synthesis by beta-cells impairs insulin synthesis, and that replenishing cholesterol restores the insulin secretion. Green tea contains this type of inhibitor, but its use has nevertheless been associated with a reduced risk of diabetes. Caffeine is likely to be the main protective substance in these foods.

Although antioxidants can be protective against diabetes, not all things sold as "antioxidants" are safe; many botannical "antioxidants" are estrogenic. Hundreds of herbal products can lower blood sugar, but many of them are simply toxic, and the reduction of blood glucose can make some problems worse.

The supplements I mention above--including caffeine--have antiinflammatory, antioxidative and energy-promoting effects. Inflammation, interfering with cellular energy production, is probably the essential feature of the things called diabetes.

Aspirin has a very broad spectrum of antiinflammatory actions, and is increasingly being recommended for preventing complications of diabetes. One of the consequences of inflammation is hyperglycemia, and aspirin helps to correct that (Yuan, et al., 2001), while protecting proteins against oxidative damage (Jafarnejad, et al, 2001).

If Dr. Budd's thinking (and results) had been more widely accepted when his publications appeared, thinking about "diabetes" might have led to earlier investigation of the syndromes of stress and tissue wasting, with insulin being identified as just one of many regulatory substances, and a large amount of useless and harmful activity treating hyperglycemia as the enemy, rather than part of an adaptive reaction, might have been avoided.

Protective CO2 and aging

The therapeutic effects of increasing carbon dioxide are being more widely recognized in recent years. Even Jane Brody, the NY Times writer on health topics, has favorably mentioned the use of the Buteyko method for asthma, and the idea of "permissive hypercapnia" during mechanical ventilation, to prevent lung damage from excess oxygen, has been discussed in medical journals. But still very few biologists recognize its role as a fundamental, universal protective factor. I think it will be helpful to consider some of the ways carbon dioxide might be controlling situations that otherwise are poorly understood.

The brain has a high rate of oxidative metabolism, and so it forms a very large proportion of the carbon dioxide produced by an organism. It also governs, to a great extent, the metabolism of other tissues, including their consumption of oxygen and production of carbon dioxide or lactic acid. Within a particular species, the rate of oxygen consumption increases in proportion to brain size, rather than body weight. Between very different species, the role of the brain in metabolism is even more obvious, since the resting metabolic rate corresponds to the size of the brain. For example, a cat's brain is about the size of a crocodile's, and their oxygen consumption at rest is similar, despite their tremendous difference in body size.

Stress has to be understood as a process that develops in time, and the brain (especially the neocortex and the frontal lobes) organizes the adaptive and developmental processes in both the spatial and temporal dimensions. The meaning of a situation influences the way the organism responds. For example, the stress of being restrained for a long time can cause major gastrointestinal bleeding and ulcerization, but if the animal has the opportunity to bite something during the stress (signifying its ability to fight back, and the possibility of escape) it can avoid the stress ulcers.

The patterning of the nervous activity throughout the body governs the local ability to produce carbon dioxide. When the cortex of the brain is damaged or removed, an animal becomes rigid, so the cortex is considered to have a "tonic inhibitory action" on the body. But when the nerves are removed from a muscle (for example, by disease or accident), the muscle goes into a state of constant activity, and its ability to oxidize glucose and produce carbon dioxide is reduced, while its oxidation of fatty acids persists, increasing the production of toxic oxidative fragments of the fatty acids, which contributes to the muscle's atrophy.

The organism's intentions, expectations, or plans, are represented in the nervous system as a greater readiness for action, and in the organs and tissues controlled by the nerves, as an increase or decrease of oxidative efficiency, analogous to the differences between innervated and denervated muscles. This pattern in the nervous system has been called "the acceptor of action," because it is continually being compared with the actual situation, and being refined as the situation is evaluated. The state of the organism, under the influence of a particular acceptor of action, is called a "functional system," including all the components of the organism that participate most directly in realizing the intended adaptive action.

The actions of nerves can be considered anabolic, because during a stressful situation in which the catabolic hormones of adaption, e.g., cortisol, increase, the tissues of the functional system are protected, and while idle tissues may undergo autophagy or other form of involution, the needs of the active tissues are supplied with

nutrients from their breakdown, allowing them to change and, when necessary, grow in size or complexity.

The brain's role in protecting against injury by stress, when it sees a course of action, has a parallel in the differences between concentric (positive, muscle shortening) and eccentric (negative, lengthening under tension) exercise, and also with the differences between innervated and denervated muscles. In eccentric exercise and denervation, less oxygen is used and less carbon dioxide is produced, while lactic acid increases, displacing carbon dioxide, and more fat is oxidized. Prolonged stress similarly decreases carbon dioxide and increases lactate, while increasing the use of fat.

Darkness is stressful and catabolic. For example, in aging people, the morning urine contains nearly all of the calcium lost during the 24 hour period, and mitochondria are especially sensitive to the destructive effects of darkness. Sleep reduces the destructive catabolic effects of darkness. During the rapid-eye-movement (dreaming) phase of sleep, breathing is inhibited, and the level of carbon dioxide in the tissues accumulates. In restful sleep, the oxygen tension is frequently low enough, and the carbon dioxide tension high enough, to trigger the multiplication of stem cells and mitochondria.

Dreams represent the "acceptor of action" operating independently of the sensory information that it normally interacts with. During dreams, the brain (using a system called the Ascending Reticular Activating System) disconnects itself from the sensory systems. I think this is the nervous equivalent of concentric/positive muscle activity, in the sense that the brain is in control of its actions. The active, dreaming phase of sleep occurs more frequently in the later part of the night, as morning approaches. This is the more stressful part of the night, with cortisol and some other stress hormones reaching a peak at dawn, so it would be reasonable for the brain's defensive processes to be most active at that time. The dreaming process in the brain is associated with deep muscle relaxation, which is probably associated with the trophic (restorative) actions of the nerves.

In ancient China the Taoists were concerned with longevity, and according to Joseph Needham (*Science and Civilization in China*) their methods included the use of herbs, minerals, and steroids extracted from the urine of children. Some of those who claimed extreme longevity practiced controlled breathing and tai chi (involving imagery, movement, and breating), typically in the early morning hours, when stress reduction is most important. As far as I know, there are no studies of carbon dioxide levels in practitioners of tai chi, but the sensation of warmth they typically report suggests that it involves hypoventilation.

In the 1960s, a Russian researcher examined hospital records of measurements of newborn babies, and found that for several decades the size of their heads had been increasing. He suggested that it might be the result of increasing atmospheric carbon dioxide.

The experiences and nutrition of a pregnant animal are known to affect the expression of genes in the offspring, affecting such things as allergies, metabolic rate, brain size, and intelligence. Miles Storfer (1999) has reviewed the evidence for epigenetic environmental control of brain size and intelligence. The main mechanisms of epigenetic effects or "imprinting" are now known to involve methylation and acetylation of the chromosomes (DNA and histones).

Certain kinds of behavior, as well as nutrition and other environmental factors, increase the production and retention of carbon dioxide. The normal intrauterine level of carbon dioxide is high, and it can be increased or decreased by changes in the mother's physiology. The effects of carbon dioxide on many biological processes involving methylation and acetylation of the genetic material suggest that the concentration of carbon dioxide during gestation might regulate the degree to which parental imprinting will persist in the developing fetus. There is some evidence of increased demethylation associated with the low level of oxygen in the uterus (Wellman, et al., 2008). A high metabolic rate and production of carbon dioxide would increase the adaptability of the new organism, by decreasing the limiting genetic imprints.

A quick reduction of carbon dioxide caused by hyperventilation can provoke an epileptic seizure, and can increase muscle spasms and vascular leakiness, and (by releasing serotonin and histamine) contribute to inflammation and clotting disorders. On a slightly longer time scale, a reduction of carbon dioxide can increase the production of lactic acid, which is a promoter of inflammation and fibrosis. A prolonged decrease in carbon dioxide can increase the susceptibility of proteins to glycation (the addition of aldehydes, from polyunsaturated fat peroxidation or methylglyoxal from lactate metabolism, to amino groups), and a similar process is likely to contribute to the methylation of histones, a process that increases with aging. Histones regulate genetic activity.

With aging, DNA methylation is increased (Bork, et al., 2009). **I suggest that methylation stabilizes and protects cells when growth and regeneration aren't possible (and that it's likely to increase when CO2 isn't available).** Hibernation (Morin and Storey, 2009) and sporulation (Ruiz-Herrera, 1994; Clancy, et al., 2002) appear to use methylation protectively.

Parental stress, prenatal stress, early life stress, and even stress in adulthood contribute to "imprinting of the genes," partly through methylation of DNA and the histones.

Methionine and choline are the main dietary sources of methyl donors. Restriction of methionine has many protective effects, including increased average (42%) and maximum (44%) longevity in rats (Richie, et al., 1994). Restriction of methyl donors causes demethylation of DNA (Epner, 2001). The age accelerating effect of methionine might be related to disturbing the methylation balance, inappropriately suppressing cellular activity. Besides its effect on the methyl pool, methionine inhibits thyroid function and damages mitochondria.

The local concentration of carbon dioxide in specific tissues and organs can be adjusted by nervous and hormonal activation or inhibition of the carbonic anhydrase enzymes, that accelerate the oonversion of CO2 to carbonic acid, H2CO3. The activity of carbonic anhydrase can determine the density and strength of the skeleton, the excitability of nerves, the accumulation of water, and can regulate the structure and function of the tissues and organs.

Ordinarily, carbon dioxide and bicarbonate are thought of only in relation to the regulation of pH, and only in a very general way. Because of the importance of keeping the pH of the blood within a narrow range, carbon dioxide is commonly thought of as a toxin, because an excess can cause unconsciousness and acidosis. But increasing carbon dioxide doesn't necessarily cause acidosis, and acidosis caused by carbon dioxide isn't as harmful as lactic acidosis.

Frogs and toads, being amphibians, are especially dependent on water, and in deserts or areas with a dry season they can survive a prolonged dry period by burrowing into mud or sand. Since they may be buried 10 or 11 inches below the surface, they are rarely found, and so haven't been extensively studied. In species that live in the California desert, they have been known to survive 5 years of burial without rainfall, despite a moderately warm average temperature of their surroundings. One of their known adaptations is to produce a high level of urea, allowing them to osmotically absorb and retain water. (Very old people sometimes have extremely high urea and osmotic tension.)

Some laboratory studies show that as a toad burrows into mud, the amount of carbon dioxide in its tissues increases. Their skin normally functions like a lung, exchanging oxygen for carbon dioxide. If the toad's nostrils are at the surface of the mud, as dormancy begins its breathing will gradually slow, increasing the carbon dioxide even more. Despite the increasing carbon dioxide, the pH is kept stable by an increase of bicarbonate (Boutilier, et al., 1979). A similar increase of bicarbonate has been observed in hibernating hamsters and doormice.

Thinking about the long dormancy of frogs reminded me of a newspaper story I read in the 1950s. Workers breaking up an old concrete structure found a dormant toad enclosed in the concrete, and it revived soon after being released. The concrete had been poured decades earlier.

Although systematic study of frogs or toads during their natural buried estivation has been very limited, there have been many reports of

accidental discoveries that suggest that the dormant state might be extended indefinitely if conditions are favorable. Carbon dioxide has antioxidant effects, and many other stabilizing actions, including protection against hypoxia and the excitatory effects of intracellular calcium and inflammation (Baev, et al., 1978, 1995; Bari, et al., 1996; Brzecka, 2007; Kogan, et al., 1994; Malyshev, et al., 1995).

When mitochondria are "uncoupled," they produce more carbon dioxide than normal, and the mitochondria produce fewer free radicals. Animals with uncoupled mitochondria live longer than animals with the ordinary, more efficient mitochondria, that produce more reactive oxidative fragments. One effect of the high rate of oxidation of the uncoupled mitochondria is that they can eliminate polyunsatured fatty acids that might otherwise be integrated into tissue structures, or function as inappropriate regulatory signals.

Birds have a higher metabolic rate than mammals of the same size, and live longer. Their tissues contain fewer of the highly unsaturated fatty acids. Queen bees, which live many times longer than worker bees, have mainly monounsaturated fats in their tissues, while the tissues of the short-lived worker bees, receiving a different diet, within a couple of weeks of hatching will contain highly unsaturated fats.

Bats have a very high metabolic rate, and an extremely long lifespan for an animal of their size. While most animals of their small size live only a few years, many bats live a few decades. Bat caves usually have slightly more carbon dioxide than the outside atmosphere, but they usually contain a large amount of ammonia, and bats maintain a high serum level of carbon dioxide, which protects them from the otherwise toxic effects of the ammonia.

The naked mole rat, another small animal with an extremely long lifespan (in captivity they have lived up to 30 years, 9 or 10 times longer than mice of the same size) has a low basal metabolic rate, but I think measurements made in laboratories might not represent their metabolic rate in their natural habitat. They live in burrows that are kept closed, so the percentage of oxygen is lower than in the outside air, and the percentage of carbon dioxide ranges from 0.2% to 5% (atmospheric CO2 is about 0.038%). The temperature and humidity in their burrows can be extremely high, and to be very meaningful their metabolic rate would have to be measured when their body temperature is raised by the heat in the burrow.

When they have been studied in Europe and the US, there has been no investigation of the effect of altitude on their metabolism, and these animals are native to the high plains of Kenya and Ethiopia, where the low atmospheric pressure would be likely to increase the level of carbon dioxide in their tissues. Consequently, I doubt that the longevity seen in laboratory situations accurately reflects the longevity of the animals in their normal habitat.

Besides living in a closed space with a high carbon dioxide content, mole rats have another similarity to bees. In each colony, there is only one female that reproduces, the queen, and, like a queen bee, she is the largest individual in the colony. In beehives, the workers carefully regulate the carbon dioxide concentration, which varies from about 0.2% to 6%, similar to that of the mole rat colony. A high carbon dioxide content activates the ovaries of a queen bee, increasing her fertility.

Since queen bees and mole rats live in the dark, I think their high carbon dioxide compensates for the lack of light. (Both light and CO2 help to maintain oxidative metabolism and inhibit lactic acid formation.) Mole rats are believed to sleep very little. During the night, normal people tolerate more CO2, and so breathe less, especially near morning, with increased active dreaming sleep.

A mole rat has never been known to develop cancer. Their serum C-reactive protein is extremely low, indicating that they are resistant to inflammation. In humans and other animals that are susceptible to cancer, one of the genes that is likely to be silenced by stress, aging, and methylation is p53, a tumor-suppressor gene.

If the intrauterine experience, with low oxygen and high carbon dioxide, serves to "reprogram" cells to remove the accumulated effects of

age and stress, and so to maximize the developmental potential of the new organism, a life that's lived with nearly those levels of oxygen and carbon dioxide might be able to avoid the progressive silencing of genes and loss of function that cause aging and degenerative diseases.

Several diseases and syndromes are now thought to involve abnormal methylation of genes. Prader-Willi sydrome, Angelman's syndrome, and various "autistic spectrum disorders," as well as post-traumatic stress disorder and several kinds of cancer seem to involve excess methylation.

Moderate methionine restriction (for example, using gelatin regularly in the diet) might be practical, but if increased carbon dioxide can activate the demethylase enzymes in a controlled way, it might be a useful treatment for the degenerative diseases and for aging itself.

The low carbon dioxide production of hypothyroidism (e.g., Lee and Levine, 1999), and the respiratory alkalosis of estrogen excess, are often overlooked. An adequate supply of calcium, and sometimes supplementation of salt and baking soda, can increase the tissue content of CO2.

Adaptive mechanisms may diminish the detrimental effects of recurrent nocturnal hypoxia in obstructive sleep apnea (OSA). The potential role of elevated carbon dioxide (CO2) in improving brain oxygenation in the patients with severe OSA syndrome is discussed. CO2 increases oxygen uptake by its influence on the regulation of alveolar ventilation and ventilation-perfusion matching, facilitates oxygen delivery to the tissues by changing the affinity of oxygen to hemoglobin, and increases cerebral blood flow by effects on arterial blood pressure and on cerebral vessels. Recent clinical studies show improved brain oxygenation when hypoxia is combined with hypercapnia. Anti-inflammatory and protective against organ injury properties of CO2 may also have therapeutic importance. These biological effects of hypercapnia may improve brain oxygenation under hypoxic conditions. This may be especially important in patients with severe OSA syndrome.

Tl128@columbia.edu PURPOSE: Patients with severe hypothyroidism present unique challenges to anesthesiologists and demonstrate much increased perioperative risks. Overall, they display

increased sensitivity to anesthetics, higher incidence of perioperative cardiovascular morbidity, increased risks for postoperative ventilatory failure and other physiological derangements. The previously described physiological basis for the increased incidence of postoperative ventilatory failure in hypothyroid patients includes decreased central and peripheral ventilatory responses to hypercarbia and hypoxia, muscle weakness, depressed central respiratory drive, and resultant alveolar hypoventilation. These ventilatory failures are associated most frequently with severe hypoxia and carbon dioxide (CO2) retention. The purpose of this clinical report is to discuss an interesting and unique anesthetic presentation of a patient with severe hypothyroidism. CLINICAL FEATURES: We describe an unique presentation of ventilatory failure in a 58 yr old man with severe hypothyroidism. He had exceedingly low perioperative respiratory rate (3-4 bpm) and minute ventilation volume, and at the same time developed primary acute respiratory alkalosis and associated hypocarbia (P(ET)CO2 approximately 320-22 mmHg). CONCLUSION: Our patient's ventilatory failure was based on unacceptably low minute ventilation and respiratory rate that was unable to sustain adequate oxygenation. His profoundly lowered basal metabolic rate and decreased CO2 production, resulting probably from severe hypothyroidism, may have resulted in development of acute respiratory alkalosis in spite of concurrently diminished minute ventilation.

The orchestrated expression of genes is essential for the development and survival of every organism. In addition to the role of transcription factors, the availability of genes for transcription is controlled by a series of proteins that regulate epigenetic chromatin remodeling. The two most studied epigenetic phenomena are DNA methylation and histone-tail modifications. Although a large body of literature implicates the deregulation of histone acetylation and DNA methylation with the pathogenesis of cancer, recently epigenetic mechanisms have also gained much attention in the neuroscientific community. In fact, a new field of research is rapidly emerging and there is now accumulating evidence that the molecular machinery that regulates histone acetylation and DNA methylation is intimately involved in synaptic plasticity and is essential for learning and memory. Importantly, dysfunction of epigenetic gene expression in the brain might be involved in neurodegenerative and psychiatric diseases. In particular, it was found that inhibition of histone deacetylases attenuates synaptic and neuronal loss in animal models for various neurodegenerative diseases and improves cognitive function. In this article, we will summarize recent data in the novel

field of neuroepigenetics and discuss the question why epigenetic strategies are suitable therapeutic approaches for the treatment of brain diseases.

Neurogenesis in the adult mammalian brain involves activity-dependent expression of genes critical for the proliferation of progenitors and for neuronal maturation. A recent study suggests that the stress response gene Gadd45b (growth arrest and DNA-damage-inducible protein 45 beta) can be transiently induced by neuronal activity and may promote adult neurogenesis through dynamic DNA demethylation of specific gene promoters in adult hippocampus. These results provide evidence supporting the provocative ideas that active DNA demethylation may occur in postmitotic neurons and that DNA methylation-mediated dynamic epigenetic regulation is involved in regulating long-lasting changes in neural plasticity in mammalian brains.

Cascara, energy, cancer and the FDA's laxative abuse

The medical culture and the general culture share some attitudes about the nature of the most common ailments--colds, cancer, arthritis, constipation, heart problems, etc., and they often agree about which things can be treated at home, and which require special medical care.

These background ideas are important because they influence the actions of insurance companies, legislators, and regulatory agencies. They also influence the judgments people make about their own health, and, too often, the way physicians treat their patients.

The prevalence of chronic constipation in North America has been estimated to be 27%, and in a ten year study, the occurrence of new cases was about 16%.--the prevalence increases with aging. In some studies, women are 3 times as likely as men to suffer from constipation. A recent Canadian article commented that "While chronic constipation (CC) has a high prevalence in primary care, there are no existing treatment recommendations to guide health care professionals."

Almost everyone in the US is familiar with the idea of "laxative abuse," of using laxatives when they aren't absolutely necessary, and with the idea that chronic laxative use will create a dependency, the way an addictive drug does. Contemporary doctors are likely to prescribe stool softeners for constipated old people, rather than "stimulant laxatives," probably because "softener" doesn't have the pejorative connotation that "stimulant drug" has--not because there is a scientific basis for the choice.

Many doctors advise constipated patients to drink more water and exercise. While there is some physiological basis for recommending exercise, the advice to drink more water is simply unphysiological. A study in Latin America found no evidence of benefit from either of those recommendations, and recommended the use of fiber in the diet. The right kind of fiber can benefit a variety of bowel problems. However, some types of fiber can exacerbate the problem, and some types (such as oat bran) have been found to increase bowel cancer in animal studies.

Despite the greater prevalence of constipation in women and older people, even specialists in gastroenterology are very unlikely to consider the role of hypothyroidism or other endocrine problems in chronic constipation.

Because of the cultural clichés about constipation--that it's caused by not eating enough fiber or drinking enough water, for example--and the belief that it's not very important, there is seldom an effort made to understand the actual condition of the intestine, and the causes of the problem.

Aging and stress increase some of the inflammatory mediators, tending to reduce the barrier function of the bowel, letting larger amounts of bacterial toxins enter the bloodstream, interfering with energy metabolism, creating inflammatory vicious circles of increasing leakiness and inflammation.

Often people visualize something like a sausage casing when they think of the intestine, but when the intestine is becoming inflamed its wall may swell to become an inch thick. As it thickens, the channel narrows to a few millimeters in diameter, and may even close in some regions. In the swollen, edematous, inflamed condition the contractile mechanism of the smooth muscle is impaired. The failure of contraction is caused by the same structural changes that increase permeability. (Garcia, et al., 1996; Skarsgard, et al., 2000; Plaku and von der Weid, 2006; Uray, et al.,

2006; Miller and Sims, 1986; Schouten, et al., 2008; Gosling, et al., 2000.)

Obviously, in the very swollen, structurally deformed intestine, with almost no lumen, neither a stimulant nor a simple fibrous bulk could restore functioning, because even with stimulation the smooth muscle is unable to contract, and the closed channel won't admit bulk. Even gas is sometimes unable to pass through the inflamed intestine. Mechanical thinking about the intestine fails when inflammation is involved; now that inflammation is known to play an important role in Alzheimer's disease and heart disease, it will be more acceptable to consider its role in constipation.

The contractile ability of smooth muscle, that's impaired by swelling and inflammation, can be restored by antiinflammatory agents, for example aspirin (or other inhibitor of prostaglandin synthesis) or antihistamines. This applies to the muscles of lymphatic vessels (Wu, et al., 2005, 2006; Gosling, 2000), that must function to reduce edema, as well as to the bowel muscles that cause peristalsis.

If someone thinks of constipation as the result of a lack of neuromuscular stimulation, then it might seem reasonable to design a drug that intensifies the contractions produced by one of the natural transmitter substances, such as serotonin, histamine, or acetylcholine. That's apparently what Novartis did, with tegaserod, a drug that increases the bowel's sensitivity to serotonin. That drug, called Zelnorm, was approved by the FDA in 2002, after a couple of years of publications praising it. At the time of its approval, there was already evidence that people using it were more likely to have abdominal surgery, especially for gallbladder disease, and there was doubt about its effectiveness.

Strangely, the drug was approved to be used for only 4 to 6 weeks, taking two tablets daily without interruption. When patients benefitted from the first treatment, they might be eligible for an additional 4 to 6 weeks, but then it would be necessary for them to find another way to deal with their constipation.

Zelnorm side effects: abdominal pain, chest pain, flushing, facial edema, hypertension, hypotension, angina pectoris, syncope, arrythmia, anxiety, vertigo, ovarian cyst, miscarriage, menorrbagia, cholecystitis, appendicitis, bilirubinemia, gastroenteritis, increased creatine phosphokinase. back pain, cramps, **breast cancer, attempted suicide,** impaired concentration, increased appetite, sleep disorder, depression, anxiety, asthma, increased sweating, renal pain, polyuria. (Later, it was found to cause heart attacks and intestinal ischemia/necrosis.) Why would the FDA approve a drug, without evidence that it was more effective than harmless things that were already widely available?

Zelnorm Prices ~ In the US, Novartis estimates that Zelnorm tablets will sell for somewhere in the range of $3 to $4 each. The drug is expected to generate $1 billion in annual sales for Novartis.

During the years just before the new drug was approved, there were several publications reporting that emodin, the main active factor in cascara, a traditional laxative, had some remarkable antiviral and anticancer activities. Other studies were reporting that it protected against some known mutagens and carcinogens. Less than 3 months before approving Zelnorm, the FDA announced its Final rule [Federal Register: May 9, 2002 (Volume 67, Number 90)] "Certain Additional Over-the-Counter Drug Category II and III Active Ingredients." "the stimulant laxative ingredients aloe (including aloe extract and aloe flower extract) and cascara sagrada (including casanthranol, cascara fluidextract aromatic, cascara sagrada bark, cascara sagrada extract, and cascara sagrada fluidextract)," determining that they "are not generally recognized as safe and effective or are misbranded. This final rule is part of FDA's ongoing OTC drug product review. This rule is effective November 5, 2002."

Historically, the FDA has ruled against traditional generic drug products when the drug industry is ready to market a synthetic substitute product.

In 2007, the FDA withdrew its approval for Zelnorm, but allowed it to be licensed as an "Investigational New Drug." *"On April 2, 2008, after more than eight months of availability, the company has re-assessed the program and has made a decision to close it. Novartis is in the process of communicating this decision to physicians participating in the program. Patients who had access to Zelnorm via this program are instructed to discuss alternative treatment options with their physicians."*

Cascara and aloe are not among the treatment options approved by the FDA, so cascara isn't

widely available (though anyone can grow aloe plants easily). However, there is considerable interest in the drug industry in the possibility of developing products based on emodin, or aloe-emodin, as anticancer or antiviral drugs. Even if it were proved to be safe and effective for use as a laxative, its potential use as an alternative to extremely profitable cancer and virus treatments would make it a serious threat to the drug industry.

Although the standard medical journals have only recently begun writing about it as a cancer treatment, emodin and related chemicals have been of interest as a non-toxic way to treat cancer, allergies, and viral and bacterial diseases for a long time.

In 1900, Moses Gomberg demonstrated the synthesis of a stable free radical (triphenylmethyl), but for years many chemists believed free radicals couldn't exist. A student of Gomberg's, William F. Koch, came to believe that cellular respiration involved free radicals, and experimented with the metabolic effects of many organic molecules, quinones of several kinds, that can form free radicals, looking for the most useful ones.

For more than 50 years the U.S. Government and the main medical instititutions actively fought the idea that a free radical or quinone could serve as a biological catalyst to correct a wide variety of health problems.

A free radical has an unpaired electron. In 1944 Yevgeniy Zavoisky devised a way to measure the behavior of unpaired electrons in crystals, but it was many years before it was recognized that they are essential to cellular respiration. Alex Comfort demonstrated them in living tissue in 1959.

By the time coenzyme Q_{10}, ubiquinone, was officially discovered, Koch had moved to Brazil to continue his work with the biological effects of the quinones, including the anthraquinone compound of brazilwood, which is used as a dye. He also used a naphthoquine, lapachone. Although vitamin K was identified as a quinone (naphthoquinone) not long after coQ_{10} was found to be a ubiquitous component of the mitochondrial respiratory system, it wasn't immediately recognized as another participant in that system, interacting with coQ_{10}.

Although Koch was unable to publish in any English language medical journal after 1914, his work was widely known. In the 1930s, Albert Szent-Gyorgyi, following Koch's ideas about electrons in cells, interacting with free radicals, began working on the links between electronic energy and cellular movement. Since free (or relatively free) electrons absorb light, Szent-Gyorgyi worked with many colorful substances. When he came to the US in 1947, and wanted to expand his research, a team of professors from Harvard investigated, and told the government funding agency that his work didn't deserve support. For the rest of his life, he worked on related ideas, expanding ideas that Koch had first developed.

Emodin and the anthraquinones (and naphthoquinones, such as lapachone) weren't the reagents that Koch considered the most powerful, but emodin can produce to some degree all of the effects that he believed could be achieved by correcting the cellular respiratory apparatus: Antiinflammatory, antifibrotic (Wang, et al., 2007) antiviral, antidepressant, heart protective, antioxidant, memory enhancing, anticancer, anxiolytic and possibly antipsychotic.

Working backward from these effects, we get a better perspective on the "laxative" function of emodin and cascara. Koch and Szent-Gyorgyi believed that cellular movement and secretion were electronically regulated. In one of his demonstrations, Szent-Gyorgyi showed that muscles could be caused to contract when they were exposed to two substances which, when combined, partially exchange an electron, causing an intense color reaction, but without causing an ordinary chemical (oxidation-reduction) reaction. This kind of reaction is called a Donor-Acceptor reaction, and it is closely related to the phenomenon of semiconduction. The reacting molecules have to be exactly "tuned" to each other, allowing an electron to resonate between the molecules.

In a muscle, any D-A matched pair of molecules would cause a contraction, but the same molecules, combined in pairs that weren't exactly tuned to each other, failed to cause contraction. Szent-Gyorgyi believed that biological signal

substances operated in a similar way, by adjusting the electronic balance of cellular proteins.

An effective laxative (besides preventing inflammation) causes not only coordinated contraction of the smooth muscles of the intestine, but also adjusts secretions and absorption, so that an appropriate amount of fluid stays in the intestine, and the cells of the intestine don't become water-logged.

In the presence of bacterial endotoxin, respiratory energy production fails in the cells lining the intestine. Nitric oxide is probably the main mediator of this effect.

The shift from respiration to glycolysis, from producing carbon dioxide to producing lactic acid, involves a global change in cell functions, away from specialized differentiated functioning, toward defensive and inflammatory processes.

This global change involves a change in the physical properties of the cytoplasm, causing a tendency to swell, and to admit dissolved substances that normally wouldn't enter the cells.

The interface between the cells lining the intestine and the bacteria-rich environment involves processes similar to those in cells at other interfacial situations throughout the body--kidney, bladder, secretory membranes of glands, capillary cells, etc. The failure of the intestinal barrier is especially dangerous, because of the generalized toxic consequences, but the principles of maintaining and restoring it are general, and they have to do with the nature of life.

Some leakage from the lumen of the intestine or the lumen of a blood vessel can occur between cells, but it is often claimed that the "paracellular" route accounts for all leakage. (Anthraquinones may inhibit paracellular leakage [Karbach & Wanitschke, 1984].) When a cell is inflamed or overstimulated or fatigued, its cytoplasmic contents leak out. In that state, its barrier function is weakened, and external material can leak in. This was demonstrated long ago by Nasonov, but the "membrane" doctrine is incompatible with the facts, so the paracellular route is claimed to explain leakage. Since the cells that form the barrier begin to form regulatory substances such as nitric oxide when they are exposed to endotoxin, it is clear that major metabolic and energetic changes coincide in the cell with the observed leakiness. Permeability varies with the nature of the substance, its oil and water solubility, and the direction of its movement, arguing clearly that it isn't a matter of mere holes between cells.

Besides endotoxin, estrogen, vibrational injury, radiation, aging, cold, and hypoosmolarity, increase NO synthesis and release, and increase cellular permeabilities throughout the body.

Estrogen excess (relative to progesterone and androgens), as in pregnancy, stress, and aging, reduces intestinal motility, probably by increasing nitric oxide production. The anthraquinones inhibit the formation of nitric oxide, which is constantly being promoted by endotoxin.

Cells regulate their water content holistically, and, to a great extent, autonomously, by adjusting their structural proteins and their metabolism, but in the process they communicate with surrounding cells and with the organism as a whole, and consequently they will receive various materials needed to improve their stability, by adjusting their energy production, sensitivity, and structural composition.

When these intrinsic corrective processes are inadequate, as in hypothyroidism, with increased estrogen and serotonin, extrinsic factors, including special foods and drugs, can reinforce the adaptive mechanisms. These "adaptogens" can sometimes restore the system to perfect functioning, other times they can merely prevent further injury. Sometimes the adaptogens are exactly like those the body normally has, but that are needed in larger amounts during stress. Coenzyme Q_{10}, vitamin K, short-chain fatty acids, ketoacids, niacinamide, and glycine are examples of this sort--they are always present, but increased amounts can improve resistance to stress.

Another kind of adaptogen resembles the body's intrinsic defensive substances, but isn't produced in significant quantities in our bodies. This type includes caffeine and the anthraquinones (such as emodin) and aspirin and other protective substances from plants. These overlap in functions with some of our intrinsic regulatory substances, and can also complement each other's effects.

Emodin inhibits the formation of nitric oxide, increases mitochondrial respiration, inhibits angiogenesis and invasiveness, inhibits fatty acid

synthase (Zhang, et al., 2002), inhibits HER-2 neu and tyrosine phosphorylases (Zhang, et al., 1995, 1999), and promotes cellular differentiation in cancer cells (Zhang, et al., 1995). The anthraquinones, like other antiinflammatory substances, reduce leakage from blood vessels, but they also reduce the absorption of water from the intestine. Reduced water absorption can be seen in a slight shrinkage of cells in certain circumstances, and is probably related to their promotion of cellular differentiation.

All of these are basic antistress mechanisms, suggesting that emodin and the antiinflammatory anthraquinones are providing something central to the life process itself.

Zelnorm was said to "act like serotonin." Serotonin slows metabolism, reduces oxygen consumption, and increases free radicals such as superoxide and nitric oxide; the production of reactive oxygen species is probably an essential part of its normal function. Emodin has an opposing effect, increasing the metabolic rate. It increases mitochondrial oxygen consumption and ATP synthesis, while decreasing oxidative damage (Du and Ko, 2005, 2006; Huang, et al., 1995).

The Zelnorm episode was just an isolated case of a drug company's exploiting cultural beliefs, with the FDA providing a defensive framework, but the contrast between tegaserod and emodin hints at a deeper and more deadly problem.

W.F. Koch's approach to immunity emphasized the role of energy in maintaining the coherence of the organism, in which toxins were oxidized and made nontoxic. There was no emphasis on destruction either of bacteria or of cancer cells, but only of the toxic factors that interfered with respiration. He demonstrated that the udders of healthy cows could contain more bacteria than those with mastitis, but the bacterial toxins were absent after the cows were treated with his catalyst. He identified the "activated carbonyl group" as the essential feature of antibiotics, the same group that makes coenzyme Q_{10} function in the respiratory system.

Koch's understanding of the oxidative apparatus of life, as a matter of electron balances, involved the idea that molecules with a low ionization potential, making them good electron donors, amines specifically, interfered with respiration, while quinones, with a high affinity for electrons, making them electron acceptors, activated respiration. The toxic effects of tryptophan derivatives, indoles, and other amines related to the behavior of their electrons. (Serotonin wasn't known at the time Koch was doing his basic research.) Koch believed that similar electronic functions were responsible for the effects of viruses.

Both chemical and physical interactions of substances cause electrons to shift in each substance, according to its composition. The shift of electrons accounts for the ability of adsorbed molecules or ions to form multiple layers on a surface, and changes in the electrons of a complex biological molecule affect the shape and function not only of that molecule, but of the molecules associated with it. Interactions of the large molecules of cells, and their adsorbed substances, tend toward stable arrangements, or phases. The type of energy production, and the nature of the regulatory molecules that are present, influence the stability of the various states of an organism's cells. (For more information on cooperative adsorption, see www.gilbertling.org.)

Koch and Szent-Gyorgyi were applying to biology and medicine concepts that were simultaneously being developed in metallurgy, electrochemistry, colloid and surface science, and electronics. They were in the scientific mainstream, and it was the medical-pharmaceutical industry that moved away from this kind of exploration of the interactions of substances, electrons, and organisms.

For Koch, antibiotics and anticancer agents weren't necessarily distinct from each other, and would be expected to have other beneficial effects as well.

But an entirely different view of the immune system was taking over the medical culture just as Koch began his research. Mechnikov's morphogenic view, in which the essential function of "the immune system" was to maintain the integrity of the organism, was submerged by Ehrlich's approach, which emphasized killing pathogens, and at the same time, the genetic theory of cancer was replacing the developmental-environmental theory.

Following the early work on the carcinogenicity of estrogens, and the estrogenicity of carcinogens such as polycyclic aromatic hydrocarbons from soot, a few German and French chemists (e.g., Schmidt and the Pullmans) began calculating the high electron densities of highly reactive regions of the anthracene molecule, showing formally why certain molecules are carcinogenic.

At that time, their work was compatible with a developmental view of cancer. But the fact that the polycyclic molecules could interact with the new model of the DNA gene caused the Pullmans' work to be reduced to nothing but a minor theory of mutagenesis.

Anthraquinones, because of the presence of several oxygen molecules, had low electron densities and were stable. The tetracyclines, with related structure, have some similar properties, and are antiinflammatory, as well as antibiotic.

When a polycyclic bacterial antibiotic, adriamycin (later called doxorubicin), was found to be too toxic to use as an antibiotic, the fact that it was toxic to cancer cells caused it to be developed as a cancer drug. It continued to be widely used even after it was found to cause heart failure in many of the "cured" patients, because of its "success" in killing cancer cells.

The fact that many kinds of cancer cells can be killed by emodin makes it slightly interesting as a cancer drug, but its simple generic nature has caused the drug industry to look for a more Ehrlichian magic bullet; for example, they are still looking for ways to keep doxorubicin from destroying the heart.

Emodin isn't a magic bullet (in fact it isn't a bullet/toxin of any sort), but when combined with all the other adaptogens, it does have a place in cancer therapy, as well as in treating many other ailments.

None of the basic metaphors of mainstream medicine--receptors, lock-and-key, membrane pores and pumps--can account for the laxative, anticancer, cell-protective effects of emodin. The new interest in it provides an opportunity to continue to investigate the effects of adjusting the electrical state of the cell substance, building on the foundations created by William F. Koch, Albert Szent-Gyorgyi, and Gilbert Ling.

Living is a constant process of deciding what we are going to do. Jose Ortega y Gasset

Radiation and growth: Incoherent imprinting from inappropriate irradiation.

Agence France-Press: The Transportation Security Administration (TSA) began rolling out full-body scanners at US airports in 2007, but stepped up deployment of the devices this year when stimulus funding made it possible to buy another 450 of the advanced imaging technology scanners. Government officials have said that the scanners have been tested and meet safety standards. But Captain David Bates, president of the Allied Pilots Association, which represents pilots at American Airlines, urged members to avoid the full-body scanner. "No pilot at American Airlines should subject themselves to the needless privacy invasion and potential health risks caused by the body scanner," he said in a letter this month, which was obtained by AFP. A group of scientists at the University of California, San Francisco (UCSF) raised concerns about the "potential serious health risks" from the scanners in a letter sent to the White House Office of Science and Technology in April. Biochemist John Sedat and his colleagues said in the letter that most of the energy from the scanners is delivered to the skin and underlying tissue. "While the dose would be safe if it were distributed throughout the volume of the entire body, the dose to the skin may be dangerously high," they wrote. The scientists say the X-rays could pose a risk to everyone from travelers over the age of 65 to pregnant women and their unborn babies, to HIV-positive travelers, cancer patients and men. "Men's sexual organs are exposed to the X-rays. The skin is very thin there," Love explained.

Beginning in 1944, the US government conducted a series of 250 experiments in which large amounts of radioactive material were released into the atmosphere, to study the effects of radioactive isotopes on people, as part of a program to develop weapons that would kill or sterilize populations.

When hydrogen bombs were produced in the 1950s, the US public was told that these weapons would make nuclear war safe, because they were "clean," since fusion didn't produce the toxic isotopes produced by fission bombs. However, immense quantities of natural uranium 238 were included in those bombs, with the result that they produced extremely radioactive fallout. This was kept secret from Americans, but the Soviets were able to determine the composition of the bombs by sampling the air that circled the world.

The US Atomic Energy Commission collected information on the radioactive isotopes in human, animal, and plant tissues from around the world, in the secret project called "Project Sunshine," for the purpose of learning how many bombs could be exploded withot killing the entire world's population.

Thomas Edison, who had begun working with x-ray machines in 1895, became an opponent of their use after 1903, when one of his employees died of cancer that began in his hands and arms. By the 1930s, many people outside the medical profession were warning that diagnostic x-rays could cause accelerated aging, heart and circulatory disease, and birth defects, as well as causing cancer and leukemia. This public awareness of the danger of ionizing radiation was the reason that the government felt obliged to lie about the nature of the bombs and their effects on people and the environment. Many people, even in the US, were asking the government to stop the bomb tests, and to discuss nuclear disarmament. Two members of the US Congress (Senator Morse and Congressman Porter, both of Oregon) introduced bills in 1957 to stop the tests, but most congressmen, and President Eisenhower, believed that the US would be able to achieve a degree of technical advantage that would permit them to eliminate the Soviet Union in a first strike. This plan was closely involved with the need to study the effects of radioactive fallout on people and crops. The highest military officials were still pressing for a first strike in the 1960s (Douglas, 2008).

Science professors, including Linus Pauling, and some high school teachers tried to educate the public about the biological effects of radiation, but the US government mobilized effectively against them, for example by sending FBI agents

to make inquiries that implied that they were "disloyal citizens." Linus Pauling's passport was revoked because of his efforts to inform the public. At the same time, the Atomic Energy Agency and other branches of government, and the corporations that were involved in manufacturing bombs and nuclear power reactors, were employing experts to assure the public that ionizing radiation was absolutely harmless, below a certain level of intensity, the threshold at which harm would suddenly begin, and that below that dose, it could even be biologically beneficial.

John Gofman was one of the most visible of those government employees who argued that there was no basis for suspending atmospheric bomb tests. As the co-discoverer of protactinium-232, uranium-232, protactinium-233, and uranium-233, who later became a medical doctor, he was a favorite of the nuclear agencies for convincing the public that ionizing radiation was nothing to be feared.

In an interview several years ago, Gofman said "I was stupid in those days. In 1955, '56, people like Linus Pauling were saying that the bomb fallout would cause all this trouble. I thought, 'We're not sure. If you're not sure, don't stand in the way of progress.' I could not have thought anything more stupid in my life.

"The big moment in my life happened while I was giving a health lecture to nuclear engineers. In the middle of my talk it hit me! What the hell am I saying? If you don't know whether low doses are safe or not, going ahead is exactly wrong. At that moment, I changed my position entirely."

"There is no way I can justify my failure to help sound an alarm over these activities many years sooner than I did. I feel that at least several hundred scientists trained in the biomedical aspect of atomic energy--myself definitely included--are candidates for Nuremburg-type trials for crimes against humanity for our gross negligence and irresponsibility. Now that we know the hazard of low-dose radiation, the crime is not experimentation--it's murder."

Many ordinary people were making exactly that argument in the 1950s, but government censorship kept the most incriminating evidence from the public. The climate of intimidation spread throughout the culture, with large numbers of dissenters, especially between 1950 and 1965, losing their jobs in government, schools, universities, and industry. Now, the increasing numbers of people who don't want x-rays are still treated as crackpots.

Probably because of this continuing political-cultural situation, Gofman's recommendations in recent years have been very mild--simply for doctors to use good technology and to know what they are doing, which could lead to a ten-fold or even hundred-fold dose reduction in diagnostic x-rays. Even with such mild restraint in the use of diagnostic x-rays, Gofman's well founded estimate is that 250,000 deaths caused by radiation could be prevented annually. I believe many more deaths would be prevented if ultrasound and MRI were used consistently instead of x-rays. Using Gofman's estimate, I think we can blame at least ten million deaths on just the medical x-rays that have been used inappropriately because of the policies of the U.S. government in the last half century. That wouldn't include the deaths caused by radioactive fallout from bomb tests and leaks from nuclear power plants, or the vast numbers of people mentally impaired by all sorts of toxic radiation.

In the 1950s, many people believed that Gofman was just another government whore, like the other prominent scientists who supported atmospheric tests and argued against the "linear, no threshold" model of radiation damage. His description of a sudden recognition of the irrationality of his position is a powerful illustration of the way an authoritarian culture can affect the thought processes, but as far as I know Gofman never tried to explain his bizarre subservience to the social-political-economic power structure of US society. Most of his contemporaries failed to reconsider their actions and policies.

Some of the survivors from that period are continuing to pollute the discussion of the biological effects of radiation. Hired by the nuclear industry to present lectures to their staff, as well as to the public, they publish articles in books and magazines sponsored by the nuclear industry, and appear in advertisements for the industry.

For more than 50 years, the arguments of the pro-radiation factions have centered on a few situations, illustrations, and anecdotes that they know are effective propaganda, because each one consists of little more than a single image. These situations are predictably used to convince people that radiation exposure is harmless: A trip in an airliner, or living in Denver, exposes a person to hundreds of times more radiation than living near a nuclear reactor does; a sheet of ordinary paper stops a beam of radiation; living in homes with high radon levels prevents lung cancer; living in radioactive apartments in Taiwan prevented 96.5% of cancers; workers in the nuclear industry have a lower incidence of cancer than other workers.

These perennial arguments are now being used to sell radioactive rocks to cure cancer. The idea of "radiation hormesis," that a small amount of radiation is positively good for the health, is even being popularized by internet sites such as Dr. Mercola's.

To counter those propaganda images, the people who want to urge caution with ionizing radiation have discussed the processes that are known to occur when a certain type of radiation interacts with a certain type of substance, and have pointed out that, despite the large amount of knowledge that exists, the specificity of these interactions and the complexity of the living substance mean that science has only begun to understand the biological effects of radiation. While emphasizing the fragmentary nature of the science, a few of these people have spent years collecting the best information available on the health effects of radiation in a few well defined situations.

Ernest Sternglass is occasionally mentioned by the nuclear apologists, as a complete quack who hasn't done anything of value, and that he contradicts the authoritative conclusions of T. D. Luckey. Anyone who actually reads some of Sternglass's books and articles, and then examines Luckey's work, will understand the situation. Sternglass presents a large amount of very meaningful data, and he also describes the actions of government and industry officials who have made great efforts to hide dangerous information. Luckey repeatedly cites a few propaganda pieces as if they contained valid data, which they don't. And Luckey is apparently the best that the industry can offer.

When a physicist compares the radiation received from cosmic rays in Denver to the radiation from military or industrial nuclear fission products, implying that the "smaller dose" from artificial sources is less harmful "because it's much smaller," he is lying. A radioactive particle that decays in the body delivers most of its energy to the tissues, but external radiation of very high energy, such as cosmic rays, gamma rays, or very high voltage x-rays, delivers a smaller proportion of its energy to the tissues.

The person who demonstrates that a beam of "radiation" (which consists of alpha particles) can be stopped by a sheet of paper is illustrating the sort of thing that happens when fission occurs within the body. If an alpha particle is released inside the body, its energy will be absorbed in a very short distance, causing very great damage in a small region (Hei, et al., 1997).

People whose houses are chronically contaminated with increased levels of radon gas don't have an abnormally high incidence of lung cancer. But why would radon be expected to cause lung cancer? It's fat soluble, and it concentrates in fat tissues, bone marrow, and the brain and other nerves. Its concentration is about 10 times higher than normal in the brains of Alzheimer's and Parkinson's disease patients (Momcilovic & Lykken, 2007), and maps of the incidence of Alzheimer's disease in the US coincide with maps of radon emissions. People who talk about the negative association of lung cancer with radon exposure clearly aren't interested in learning the harmful effects of radon exposure.

The original article about the radioactive apartments in Taiwan, whose occupants had only 3.5% as many cases as would be expected from the rate in the general population, was written by W. L. Chen and 13 co-authors. Chen and at least 12 of his co-authors were closely associated with the nuclear industry or the military. The article gives no definite information about the distribution of the radiation within the apartments, about

the general health and mortality rate of the residents, or about the ages of the tenants. The article was published in the ***Journal of the Association of American Physicians and Surgeons.*** (This magazine was formerly named ***Medical Sentinel.)*** The ***New York Times*** described AAPS as an "ultra-right-wing . . . political-economic rather than a medical group," and most of the articles are advocating extreme economic and political action. Yet most of the people who argue that Chen's article is evidence of the harmlessness, or beneficial effects, of radiation, including T. D. Luckey, list it in their references, as if were a scientific report.

Even the mainstream professional journals haven't had a good record for objectivity. R. E. Alexander, a former chairman of the Health Physics Society's public relations committee, told the society's board of directors that Ernest Sternglass's work had led to publicity that was damaging to the nuclear industry. He said that the "basic publicity objective" of the Society was "to let the public know that due to a frankly acknowledged need, we have a new technology, health physics, which will permit them to enjoy the benefits of nuclear energy safely." Facts about the harmful effects of radiation were harmful to the Society, but "while we try to avoid publicizing papers that do not contribute to our basic objective, there is no way to prevent such publicity absolutely."

From my own experience, I think that kind of deference to economic interests is common in the major science journals in all fields.

Another journal that serves the industry is ***Radiation Protection Management.***

One of the current authors in ***RPM*** is Mark Hart, who mentions how he tries to prevent his audience from thinking "this guy must work for the government." He arranges to have himself introduced as a person who is displaying his personal collection of antiques (radioactive antiques), and that he has taken his vacation time to present the lecture.

"This demonstrated that I was not being paid by the Laboratory [Lawrence National Radiation Lab] to give the talk." "I make a point of separating the contents of my presentation from whatever the stance of my employer may be on this subject. I point out that the information that I will present is not my perspective nor the result of any research that I have conducted: I am only presenting a 'book report,' a very elaborate book report with examples on display that are integrated into the talk. I am presenting the very same information that the audience can read for themselves. To this end the presentation encompasses the range of authors from Gofman (linear hypothesis) to Luckey (hormesis) and ties historical experience to the common understanding of radiation and radioactivity." "We must also remember that credibility is lost if the audience is taken too far, too fast." "For instance, tell an audience that more people have died in the United States from airbags than died at the Chernobyl accident."

Hart's comment on the linear hypothesis: "This conservative approach was adopted assuming *any* amount of radiation would put a person at a quantifiable risk. There is little direct evidence of this, and there is disagreement about its veracity, even among radiation professionals." His use of the word "veracity" in relation to evidence implies that some professionals are lying about the evidence, but his context makes it clear that he is referring to people like Gofman.

In 1959, I suggested that my students, reading about the effects of radiation, should notice who the authors worked for. It was immediately obvious to them that government employees never mentioned that radiation could be harmful.

The people in the various professions who insist that "small" amounts of radiation are perfectly safe, or beneficial, seldom say much about the mechanisms involved in the harm or benefit of radiation. They suggest that the ionizing radiation stimulates mechanisms that repair damaged genes, when it damages them, or that it "stimulates the immune system." The very old idea, developed more than 80 years ago, that radiation's biological effect is produced exclusively by causing genetic damage, continues to be central to their thinking. This view dominates the thinking of dentists and physicians, as well as those in the business of "protecting public health."

At the beginning of the 20th century (e.g., H.J. Muller, 1910, 1921) when nothing was known about the physical or chemical nature of "the gene," many biologists committed themselves to the belief that "the gene is the basis of life."(Ann Rev of Genetics vol. 2:1-10, 1968, G. Pontecorvo, Hermann Joseph Muller; page 1). When it was discovered that x-rays produced mutations it seemed obvious that it was because they changed the "genes," and later when genes came to be identified with DNA, it was believed that radiation had its biological effects because of its effects on DNA, which continued to be thought of as "the basis of life."

The idea is that at the moment radiation is absorbed by a tissue, a DNA-gene is damaged, or not. Studies of DNA in isolation have contributed to some mistaken ideas about radiation safety; at one time the mere size of the DNA molecule was thought to determine an organism's sensitivity to radiation. In living cells, according to the older explanation, if the amount of DNA damage isn't too great, it will be repaired, and the radiation will have had no effect at all. A greater amount of DNA damage might be incorrectly repaired, producing a mutation, that could produce cancer, or, if the gonads were exposed to radiation, an inherited defect could be produced. Any damage would be instantaneous and local, and the repair would take place within minutes or hours, so by analyzing the DNA (usually just looking for structural changes in chromosomes), the degree of damage could be determined soon after the exposure.

This localized "genetic" explanation for the harmful effects of radiation was the predominant ideology of Anglo-American biology. William Bateson, who promoted the genetic doctrine of Gregor Mendel, and his followers such as Charles Davenport, wanted to deny absolutely the possibility that environmental influences could influence traits such as intelligence; each trait was determined by a gene. At the same time, 1902-1914, Theodor Boveri was explaining the formation of cancer by radiation or chemical carcinogens in terms of an induced imbalance of chromosomes, produced by changes in the process of cell division. The sorting of chromosomes during cell division became unstable under the influence of various harmful factors. Boveri saw that disturbing the chromosomes of an embryo could cause cells to stray out of their normal developmental path, and reasoned that this is similar to what happens in cancer--a disorganization of cellular interactions. But William Bateson didn't acknowledge that chromosomes carried genetic information until 1922, and his influence greatly retarded Anglo-American study of the biology of chromosomes, and of cancer.

This old idea (Boveri's) of genomic or chromosomal instability has become central to understanding the real effects of radiation on organisms. The fact that bacteria and other single-cell organisms contain DNA isn't enough to allow them to be considered as models for understanding the biological effects of radiation, because the existence of more complex organisms depends on the coordination of cells, based on signals and perception of wholes. The nature and the quality of our development depends on the degree of our cells' vigor and sensitivity in responding to, maintaining, and creating our long-range coherence. The sorting of chromosomes is one of the processes affected by the cells' basic vitality.

On the intracellular level, organization and sensitivity depend first on the interactions of water, electrons, and proteins, supported by the modifying effects of carbon dioxide, sugars, fats, nucleic acids, salts, and other substances. The crucial regulatory processes occur within a narrow range of energy changes. Interacting cells communicate their needs by excitatory signals that mobilize other parts of the system to make adaptations. Excitatory signals imposed arbitrarily from the outside on the adapting organism can create a state of arousal without a defined purpose, meaning that in the absence of a goal that can be achieved, the excited state may expend resources that could have been used productively in other ways.

Ionizing radiation is one source of such misleading excitatory signals, and even apart from its ionizing effects, it is likely to transmit enough extraneous excitation to the delicately balanced living state to change its organization and sensitivity.

When a man receives ionizing radiation to the head (Tamminga, et al., 2008), his sperms are destabilized in such a way that they are able to carry the instability with them into the fertilized ovum and the developing offspring, increasing the risk of developing leukemia.

Leonell Strong, who had studied genetics with T.H. Morgan and began breeding a strain of cancer-prone mice in 1921 for use in cancer and genetic research, gradually began thinking in terms of environmentally induced genetic instability. Excessive estrogen, and changes in the metabolism of the liver were the two factors that he focused on. He found that if a pregnant cancer-prone mouse received injections of a liver extract, several generations of the descendants would be free of cancer. The genetic instability that caused them to reliably develop mammary cancer was an inherited metabolic condition which could be corrected by a metabolic treatment.

It had been known for several decades that both estrogen and ionizing radiation produced cancer, when in 1971 Segaloff and Maxfield showed that they are synergistic. Irradiation produced cancer much more quickly when the rats had been treated with estrogen. In 1973, Segaloff treated 3 groups of rats, (1) with estrogen and radiation (800 R of X-rays to half of the body), or (2) with estrogen, radiation and progesterone, or (3) with just radiation and progesterone. As in the earlier experiment, many tumors quickly appeared on the side of the body that received the radiation in most of the animals of group 1, but in group 2 only one eighth as many tumors appeared in the animals that received progesterone. In the third group, no tumors appeared in the irradiated animals that received progesterone.-

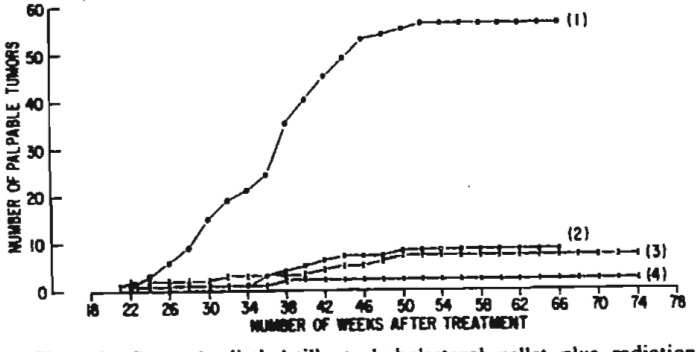

Chart 1. ***Curve 1***, **diethylstilbestrol-cholesterol pellet plus radiation (radiated side);** ***Curve 2***, **diethylstilbestrol-cholesterol pellet plus radiation (nonradiated side);** ***Curve 3***, **diethylstilbestrol-cholesterol pellet plus progesterone pellet plus radiation (radiated side);** ***Curve 4***, **diethylstilbestrol-cholesterol pellet plus progesterone pellet plus radiation (nonradiated side).**

This protective action of progesterone against radiation implies that X-rays have "estrogenic" effects on the body. This had previously been demonstrated very literally, when it was found that irradiating any part of the body of a female animal caused it to go into estrus, behaviorally as well as physiologically and biochemically.

Toxic heavy metals can also sensitize animals to radiation (and some metals, such as cadmium, have estrogenic effects). Stress of any sort tends to increase the formation of estrogen, and estrogen activates many mediators of inflammation.

Forty years ago, all carcinogens were dogmatically considered to be mutagens, but gradually the idea of "non-genotoxic carcinogenesis" has been recognized, along with the idea of genetic instability. Estrogen is typical of this type of carcinogen. Heat exposure, "serum starvation," and the tumor microenvironment are examples of non-genotoxic factors that can induce the instability (Li, et al., 2001). If the local environment of the tumor is carcinogenic, the tumor could grow by "induction" of defects in normal cells, rather than just by multiplication of its own cells. (I have proposed that carbon monoxide produced by a tumor could be a factor in the enlargement of the tumor, by induction of stress in surrounding cells.)

When destabilizing factors are transmitted from cells that were damaged, for example by irradiation, to other cells that weren't exposed to the radiation, but which then undergo changes similar to those of the exposed cells, these changes are called "bystander effects." Besides being transmitted from one part of the body to another, for example from the head to the reproductive organs, these effects can even be transmitted from one animal to another, for example from fish exposed to radiation to other fish which enter water after the exposed fish have been in it (Mothersill, et al., 2007). Serotonin has been identified as one of the substances transmitting the effect (Poon, et al., 2007). In some situations, the transmitted factors include nitric oxide and "persistent" free radicals (Harada, et al. 2008).

Besides transmitting the destabilizing effects through space, the effects can also be transmitted through time. Between 1988 and 1992, people

who survived the atomic bomb in Hiroshima in 1945 were tested for signs of inflammation, and their leukocyte counts, erythrocyte sedimentation rate, alpha-1 globulin, alpha-2 globulin, and sialic acid levels were increased in proportion to the amount of radiation they had been exposed to (Neriishi, et al., 2001). Twenty years after people were exposed to radiation by working at the reactor site after the accident at Chernobyl, their blood serum was compared to that of people who weren't exposed. Serum from the exposed workers caused chromosome damage and loss of viability in test cells (Marozik, et al., 2007).

G. Csaba's idea of hormonal imprinting is that a pattern is formed in the cytoplasm in response to the environment, and that this pattern can be passed from generation to generation if it is useful (Csaba, 1986). The persistent bystander and even transgenerational effects of radiation can be thought of as a kind of negative imprinting, a disruption of useful cytoplasmic patterning. The outcome of any cellular destabilization can be influenced by many things, even years or generations later. Even seemingly normal identical twins and cloned animals have recognizable differences, resulting from slight instabilities in the imprintable factors that regulate development (Dolinoy, et al., 2007; Weidman, et al., 2007; de Montera, et al., 2010; Wong, et al., 2010; Zwijnenburg, et al., 2010).

Prenatal or neonatal exposure to extremely small amounts of the estrogenic substances used in plastics, nonylphenol and bisphenol-A, have been found to greatly increase adult sensitivity to estrogen (Wadia, et al., 2007; Soto, et al., 2008). The synergy of estrogen and ionizing radiation suggests that early exposure to either could increase adult sensitivity to both.

The bystander effects include alterations in energy metabolism (Nugent, et al., 2010), movement, mitosis, and cellular orientation or perspective. Cells have different degrees of mobility, from muscle and bone cells to leukocytes, and the integrity of the organism depends on the appropriateness of their movements. Cells have to know where they are, and when, to coordinate their activities in space and time, knowing not only when to divide, but exactly how to orient the direction in which the division will occur.

Although I consider every cell to be a potential stem cell, it's helpful to consider the nature of the "stem cell function" in a general sense. The cells in the basal layer of the skin or intestine, for example, are well known stem cells. With each division, one daughter cell stays in place as a stem cell, while the other migrates toward the surface, as a differentiating and functioning replacement cell. (In the brain, cells migrate from a zone around the ventricles into the brain.) This is an asymmetric division, which must be oriented exactly, so that the basal layer continues to contain stem cells, rather than differentiated cells. The extracellular matrix surrounding the "stem" cells participates in the orientation of the asymmetrical division. Without proper orientation of the cell and its matrix, tissue renewal would fail.

In the 1920s and 1930s, when the idea of developmental fields guided many areas of research, numerous biologists considered that electrical and electromagnetic fields interacted with chemical processes, permitting cells to sensitively regulate their size, shape, orientation, and interactions with their surroundings. W.F. Koch, Alexander Gurvich, Albert Szent-Gyorgyi, and G.W. Crile did many experiments demonstrating the biological effects of electrons and photons, but in the spirit of reductionism corporate science bitterly rejected their work for several decades. A few groups have been bringing their ideas up to date, in ways that help to understand bystander effects, lingering inflammatory effects, imprinting, transgenerational effects, and that suggest new types of therapy.

Gurvich, and more recently many others including F.A. Popp, have demonstrated that normal cells emit weak photons in the visible and ultraviolet spectrum. Popp's laboratory has demonstrated that DNA can "store photons," by forming stable excited electronic states between nucleotide bases. Excited states in proteins can be transmitted to other proteins (Lardinois, et al., 2003), and the water close to proteins can maintain the excited states of electrons produced by oxygen over long periods of time (Marchettini,

et al., 2010; Voeikov, 2001, 2002, 2007; Voeikov & Malenkov, 1971, Voeikov, et al., 2003).

Enzymic reactions in normal metabolism can create a variety of excited electronic states which contribute to the store of photons and electrical fields. In plants, light creates an excited electronic state in chlorophyll, which is used metabolically, generating cellular fields similar to those in animals. The random processes of free radical oxidations in unstable lipids can also create excited states and photons, but they are distinct from those produced in normal metabolism. Deeply penetrating ionizing radiation is a unique source of random excitation of electrons, contributing to the burden of random stimulation.

In the normal metabolic oxidation and reduction, orderly electrical fields are generated, and the polarity of these fields is closely related to the alignment of the parts of the cell that regulate movement and cell division. When an external electrical field is applied experimentally, the centrosome, Golgi body, microtubules and other parts of the cell align themselves with the field, the cytoplasm streams, and the cells migrate toward the external cathode.

Injured cells behave like cathodes, producing the strongly negative "injury potential." Intensely stimulated cells produce a similar field, and it has been known for many years that brain cells will migrate toward an area of excitation. But disoriented cells don't migrate appropriately.

Since the normally oriented fields are maintained by metabolically excited electrons, and govern the quality of tissue renewal, the random electronic and light activity produced by lipid peroxidation and other toxic processes threaten the basic organization of the animal or plant. Vitamin C and the intrinsic "antioxidants" protect against these electronic disturbances, and can reverse some of the bystander effects produced by radiation and other stresses.

Even ultraviolet light can produce electronic excitation and bystander effects that destabilize cells, but, unlike gamma rays and x-rays, ultraviolet light doesn't penetrate deeply into the body. In visible light, it is only the red component that can pass deeply into the tissue, and it happens that red light is able to "quench" many excited electrons, restoring them to their normal resting or ground state. In a solid material, such as a seed or hair or bone, excited electrons will persist for a long time (hours in the seed and hair, years in bone), but with a brief exposure to red light, they will return to their normal state.

This beneficial effect of the red component of sunlight helps to keep plants from being sunburned. If the red light is removed from sunlight, even the blue light by itself is quickly toxic to their mitochondria. During the night, animals' respiratory enzymes lose some of their effectiveness, possibly from the effects of random lipid peroxidation, and red light restores their activity.

Heat stress and increased pH contribute to the generation of random electronic excitation, and light is protective in plants, partly by allowing carbon dioxide to be produced. In all cells, CO2 helps to control the general electronic state, lowering the pH and protecting the essential molecules from random excitations, oxidations, and reductions.

Under natural conditions, cosmic rays are an important source of random electrical excitations. At high altitude, their high energy causes them to have a low "linear energy transfer," LET, affecting tissues only slightly as they pass through, and at sea level the secondary and tertiary rays produced from the collisions of primary cosmic rays with the atmosphere have a higher LET, which is probably responsible for the lower mortality from cancer and heart disease at high altitude. But the lower oxygen pressure at high altitude, and greater retention of carbon dioxide in the tissues, would also reduce the tissue damage from radiation.

There are two species of bacteria that can withstand extremely large doses of ionizing radiation, and carbon dioxide seems to be the crucial factor in the ability of their proteins to function, even when their DNA has been fragmented by intense ionizing radiation.

The recognition of the coherence of the organism on the molecular and electronic level makes it clear why there can be no threshold of safety for ionizing radiation, but it also suggests new

approaches to preventing and treating the developmental and degenerative diseases.

Meanwhile, people in the US are being offered CAT scans to "detect early signs of heart disease" in a test that "takes only 20 to 30 minutes," and for other trivial reasons, with the approval of state radiation regulators, and without interference from the FDA. Hundreds of people recently experienced loss of hair in a stripe around their head after having x-ray scans, when their doctors intentionally used high doses to get clearer images. Paralysis and dementia are likely to follow in a few years, but few doctors recognized their bizarre hair loss as an indication of radiation poisoning. Many hospitals use low voltage x-rays for mammograms, with high LET and increased carcinogenicity, to get better images.

In California, where hundreds of the destructive head scans were done, tort reform law means that noneconomic damages for medical malpractice are limited to $250,000, from which a successful litigant would have to pay the lawyer. Premature death or dementia would be likely to precede any legal victory.

The culture that has made these bizarre medical radiation exposures possible is being sustained and expanded every time your dentist or physician explains the safety of "digital x-rays," or "dual photon bone scans," or mammograms.

Cancer: Disorder and Energy

According to the World Health Organization, cancer is now the leading cause of death in the world. Although many "causes" are known, and despite the "War on Cancer," nothing practical has been done to reduce the incidence of cancer. Since Nixon started that war, the number of people dying annually in the US has increased faster than the population. In ancient Rome and Egypt, cancer was rare; cancer has been identified in only one Egyptian mummy. In the US and several other countries, between 2002 and 2005 there was an unprecedented decline (7% in the US) in the incidence of breast cancer, when the medical use of estrogen decreased following the Women's Health Initiative report showing that estrogen caused cancer, dementia, strokes and heart attacks. However, when the public was reassured about estrogen's safety, breast cancer incidence began increasing again each year.

The cancer industry has been flexible and imaginative in ways of presenting "age standardized" death rates to show that they are making progress against cancer, but there are philosophical and scientific problems in "oncology" (i.e., the study or treatment of lumps) that should be considered by anyone who plans to do business with that profession.

In the 19th century (in Johannes Muller's lab), cancers, like other animal tissues, were found to be made up of cells, and by 1858, all diseases were said to be caused by disturbances in cells (Rudolph Virchow). The atomic and molecular theory of matter was becoming accepted at the time that animals were found to be made up of cells, and in both cases the "elementary particles" seemed to have a special power to explain things. This idea of a cellular basis of disease gradually displaced the old idea that diseases were caused by an imbalance of the body fluids, or humors. In 1863, Virchow recognized that inflammation, involving leukocytes, was a common feature of cancer, but that aspect of his work was neglected for a long time.

Recent medical textbooks reveal no major change in the understanding of cancer since Virchow's time, except that "genes" (which weren't known during Virchow's life) gradually became the most important aspect of cells. The typical modern textbook describes the cellular disturbance of cancer as the result of an "initiating" mutation in a gene, which gives it the potential to develop into a cancer, if it subsequently is exposed to a "promoter," which causes it to multiply. In some versions of the theory, a promoter is a second mutation that causes proliferation, but in other versions the promotion is caused by chemicals binding to receptors the way hormones do, to stimulate proliferation. Typically, textbooks (and reports of continuing research) describe subsequent changes in the genes that cause a cancer to progress from a simple excess of cells through stages of increasing malignancy: hyperplasia, dysplasia, carcinoma in situ, invasive cancer.

One of the reasons that the medical understanding of cancer hasn't changed significantly since Virchow's time is that blaming misbehaving cells for causing a tumor fits into the older medical tradition, that has existed at least since the time of Hippocrates, 400 BC, which treated tumors either by cutting them out, or by burning them off with caustics. Virchow's identification of misbehaving cells provided a clear mental image of exactly what the physician must try to destroy. And it's probably hard to get interested in

something which could seriously limit your professional activities if it turned out to be true.

The "cellular basis of cancer" was developed simultaneously with the germ theory of disease, and in the case of cancer, the deviant cells came to be considered an alien substance, "not-self," analogous to infective germs. Paul Ehrlich's search for poisons that were specific for bacterial pathogens was quickly extended to the idea of finding poisons that would distinguish between cancer cells and the patient's cells.

Hippocrates' therapeutic approach to cancer may have survived for 2400 years, but the ideas of his younger contemporary, Plato, about order and causation have probably had a greater effect on medicine. Plato believed that the world of experience is inferior and accidental, and that there are timeless "Forms" that are the real substances. In the atomic theory of matter, eternal, unchanging atoms took the place of platonic forms, and there are still molecular biologists who insist that life can only be explained in terms of its constituent atoms ("What else is there but atoms?"). This philosophy of timeless forms was a deep commitment of people like Gregor Mendel and August Weismann, whose ideas dominated the thinking of early 20th century geneticists. Genes were the immutable essence of organisms, and the cells, tissues, and organs that form the organism are merely temporal and accidental. Weismann's "germ plasm" or germ line contained the immortal genes, the rest of the body lacked them, and was essentially mortal.

For most of the 20th century, the official doctrine was that most of the cells of the adult body became stationary once the body reached its adult size, and that aging consisted of the "wearing out" of those mortal cells. When a tumor, containing new cells, would appear and grow, these cells were called "immortal," because they didn't follow the rule for normal, stationary, mortal cells. Their "immortality" is often demonstrated by growing them endlessly in culture dishes. Normal cells, if they can be made to survive in a culture dish, are likely to be "transformed" into cancer, demonstrated by their ability to replicate in dishes.

This is an important ideological point, that developed as biologists were experiencing the extreme difficulty of getting cells to replicate, or even to survive, in culture dishes. It has only recently been realized that cells need more than nutritional and hormonal signals to survive in culture; they require certain textural, structural, even rhythmically repeating conditions that mimic their surroundings in the living body.

Applied to cancer, the gene theory made it seem clear that the changes occurring in tumor cells were irrevocable, and it has seemed self-evident to oncologists that the only hope the cancer patient has is for the physician to destroy every bit of the alien substance. The recurrence of a cancer that has been removed has been evidence to them that fragments had remained, or that the cancer had distributed its seeds into other parts of the body. This seems to be the necessary conclusion if cancer is "caused" by defective genes.

New ideas of causality have grown up in science beside, or within, the science culture that is committed to platonism, reductionism, and genetic determinism. A few biologists, including Ana Soto and Carlos Sonnenschein, are applying more realistic ideas of causality to ecological, developmental, and cancer research. They have said (Soto, et al., 2009) "The ecological developmental biology (eco-devo) movement rejects the notion that development is merely the unfolding of a genetic program." If events such as cancer aren't "caused by genes," understanding the causes of cancer and the appropriate ways to treat it will require more holistic ways of looking at the tumor's relation to the organism, and the organism's relation to the environment.

It has been more than 40 years since experimenters demonstrated that cancer cells could be caused to revert to normal, by changing their environment. Harry Rubin (2006) has observed that cells can accumulate hundreds of mutations, and still function normally in the organism, but when separated and grown in a culture dish their differences become obvious. The surrounding cells in the body are causing the defective cells to remain normal in appearance, function, and growth behavior, instead of acting like cancer cells, and can also cause "stem-like" cells to

differentiate appropriately.. He says "Intimate contact between the interacting cells is required to induce these changes." When stem cells enter a tumor, they don't find that regulatory, normalizing interaction with normal cells.

Work like Rubin's shows that even "myriad" mutations don't necessarily cause cancer, and another line of research shows that things which don't cause mutations can cause cancer--the "non-mutagenic carcinogens." The presence of mutations is neither sufficient nor necessary for causing cancer, but tumors do eventually accumulate serious damage, which causes most of the tumor cells to die quickly. Biological stress, or excitoxic energy deprivation, destabilizes the genome; genetic changes develop as a result of prolonged destructive influences. The "non-genotoxic" carcinogens first cause inflammation, excitation, and energy impairment, leading to fibrosis, and atrophy. Cycles of cell injury, death, and repair cause chromosomes to deteriorate as the tissue loses its organization.

When a cell is stimulated, it responds, and the response requires energy. The stronger and more continuous the stimulus, the more energy the cell needs to continue responding. In some conditions, cells can desensitize themselves, to survive in the presence of continuous stimulation or irritation, but otherwise they are killed when they don't have enough energy to keep responding.

When a nerve is stimulated and responds, a wave of negative electrical charge passes through it; the electrical field accompanies a structural change in the cytoplasm of the nerve; similar changes occur in other types of cell. Stimulation of a nerve with negative (cathodal) polarity causes swelling, stimulation with the opposite polarity causes the opposite behavior; when nerve cells are inhibited, they shrink (Tasaki and Byrne, 1980; Tasaki, et al., 1988; Tasaki, 1999).

Swelling, an increase of the water content of an area of tissue, is a general feature of inflammation (Weiss, et al., 1951), whether it's in a lump caused by a bee sting, a bruise, or hives, or a cancer. Besides the instantaneous uptake of water described by Tasaki, there are increases that continue because of metabolic and chemical changes in the irritated cell. Tasaki has used gels of synthetic polymers to demonstrate that an electrical field can cause these changes, without the need for the "chemical osmotic" changes that are customarily assumed to account for the swelling changes caused by stress (Tasaki, 2002). When the pH of a protein gel becomes more alkaline, it swells. The electrical activation of a nerve causes a quick shift towards internal alkalinity (Endres, et al., 1986), followed by a sudden increase in lactic acid production. Although increased lactic acid causes acidity of an irritated or inflamed region, the conversion of pyruvic acid to lactic acid causes the interior of the stressed cell to become more alkaline, causing it to swell. This is the same process that causes the familiar swelling of tired muscles.

If blood vessels swell, the delivery of oxygen may be restricted, and hypoxia causes more intense swelling, because more lactic acid is produced, and less oxidized. This swelling pressure resembles an increase of osmolarity. For over 100 years, it has been customary to treat shock with "isotonic" fluids, which are in balance with well oxygenated tissues, with approximately 290 milliosmoles per liter, but this usually causes edema, swelling, and weight gain. Stressed tissues have been found to be in balance with fluids of much higher osmolarity, for example 372 mOsm/L (Tranum-Jensen, et al., 1981), and sometimes much higher.

Apart from its acidity, lactic acid acts as an excitatory signal. A very slight increase above the normal amount of lactic acid in the body fluids excites sensitive cells, and the amounts reached in inflamed tissues and in cancers will excite even stable cells such as myelinated nerves (Uchida and Murao, 1975).

Cancer cells show all the signs of being intensely stimulated, and this includes a high rate of oxygen consumption (deGroof, et al., 2009). The stimulation increases the energy requirements beyond the ability of the mitochondria's capacity to meet them, leading to the production of lactate even when a normal amount of oxygen is present. Even when both glucose and oxygen are supplied (which they usually aren't), the tumor cells will consume amino acids as fuel, as well as using them as material for growth. Tumors have been

called "nitrogen traps" or "glutamine traps," but this has meaning beyond the use of the nitrogen for growth; it is involved in the energetic inefficiency of this process, and the reorganizing effects this wasteful flow of energy has on the tissue structure (Medina, 2001). When glutamine enters the Krebs cycle to be used as fuel, this interferes with the ability to oxidize glucose, causing more lactic acid to be formed, contributing to the excitation and increased energy requirement.

Lactic acid activates the other major mediators of inflammation, including prostaglandins (made from PUFA), free fatty acids (including arachidonate, that forms prostaglandins; Schoonderwoerd, et al., 1989), nitric oxide, carbon monoxide, proteolytic enzymes that degrade the extracellular matrix, TNF (Jensen, et al., 1990), hypoxia inducible factor (Lu, et al., 2002; McFate, et al., 2008), interferon, and interleukins. Arachidonic acid itself can increase lactate production (Meroni, et al., 2003). TNFalpha and interferon gamma activate lactic acid production by increasing prostaglandins (Taylor, et al., 1992).

Most of the present information about cancer cells' behavior, such as reactions to radiation and chemical toxins, has been based on the study of cells in culture dishes. For more than 70 years, it was generally believed that radiation caused mutations and cancer by directly modifying the cells' genetic material. Then, it was discovered that fresh cells that were added to a dish of irradiated cells also developed mutations. The radiation causes cells to emit excitatory, inflammatory, substances such as serotonin and nitric oxide, which injure the cells that are later put near them.

Applying this information to the existing knowledge that radiation induces cancer in animals, the doctrine of genetic determinism inferred that the radiation "bystander effect" is just another mechanism by which radiation produces the "mutant cancer cell" or clone of cancer cells. But the difference between events *in vitro* and *in vivo* is that cells which are injured in the organism immediately initiate a process of healing, and in that situation each of the substances emitted by injured cells is acting both locally and systemically to activate repair or regeneration of the damaged tissue. Cells isolated in a culture dish can't call on the organism for the necessary materials, so the responses of the "bystander" cells, leading to mutations and death, seem meaningless. The injured cells are merely toxic, rather than potentially being a stimulus to healing.

When any part of a living organism is injured, for example by x-rays or surgery, the emitted substances affect the endocrine and nervous systems, activating processes that change metabolism and behavior. The injured tissue takes on new functions, for example by locally synthesizing estrogen, cortisol (Vukelic, et al., 2011), and other hormones, as well as stimulating the normal endocrine glands to secrete them. These interactions have been generally disregarded in cancer treatment, because of the gene-centered theory of cancer, but they are essential for understanding the "malignancy" of tumors, that property that makes them likely to return after the tumor has been destroyed, and to spread to other tissues. Has anyone ever heard of a radiologist or surgeon who measured estrogen or the various mediators of inflammation before, during, and after their treatments? Long range survival after breast cancer surgery is affected by the time in the menstrual cycle when the surgery is done (Lemon, et al., 1996).

All sorts of stress, inflammation, and tissue injury increase the concentration of estrogen, both locally and systemically. Estrogen in turn produces hypoxia, swelling, lactic acid formation, and stimulates cell multiplication. Even a brief period of hypoxia will cause the secretion of lactate and other chemoattractants (Neumann, et al., 1993), which will cause cells to move into the hypoxic area from the blood stream. Although lactic acid attracts immune cells, it probably reduces their anticancer functions, and it stimulates the formation of new blood vessels, supporting continued growth and expansion of the multiplying cells (Hirschhaeuer, et al., 2011). When a tissue is being repaired normally, the new cells sense a quorum, and stop multiplying. The return of nerves to the damaged area is part of the regenerative process; nerves have inductive and stabilizing effects on differentiating cells.

These complex interactions between tumor cells and the rest of the organism are not

considered by the ideology of medical oncologists. The ruling belief is that the malignancy of cells can be determined by examining them microscopically, and that their rate of growth can be determined, and that the tumor's approximate time of origin can be estimated. After surgically removing a tumor, the administration of chemotherapy and/or radiation is governed by mathematical descriptions of the expected behavior of cancer cells.

The mathematical relation of mortality to aging was described by Benjamin Gompertz, an actuary, in 1825, based on the understanding that people become less able to resist dying as they get older. This Gompertzian growth curve, which is realistic when applied to a population of people, flies, or rabbits, was applied to tumor growth (A.K. Laird, in 1964). Gompertz' reasoning that the probability of a person's dying increases with age has nothing to do with cancer cells, and there is very little evidence that his law of growth is useful for describing tumors. Laird's evidence consisted of 19 tumor samples, taken from 10 mice, 8 rats, and a rabbit. Her suggestion that the continuing deceleration of the growth rate might represent a natural growth regulating process wasn't influential, but her use of an actuarial formula, suggesting certain properties of cancer cells, has been extremely influential. It seems to be the profession's great need for justification that has made a Law of Tumor Growth so important to them.

At the time Laird did the tumor growth study, there was considerable interest in the idea that the immune system could be induced to prevent tumor growth. In 1951, Chester Southam, of the Sloan-Kettering Institute, tested his theory of cancer immunity on hundreds of patients and prisoners, and his results were widely reported. He found that pieces of tumor implanted in healthy people caused a local intense inflammation, which healed completely after two or three weeks. In sick people, the rejection of the cancer implant took about twice as long, and in people who already had cancer, the implant was very slow to be destroyed, and sometimes it was still present when they died.

In 1889, Stephen Paget had noticed that cancers metastasize only into certain organs, and compared the cancer cells to seeds that "can only live and grow if they fall on congenial soil." While many people, like Southam, saw a failing "immune system" as part of the congenial soil, and suggested vaccination to activate an immune rejection of the tumor, others have suggested "reducing the soil to dust," making growth impossible in a more general way. Recently, this attitude has taken the form of different ways of "starving" cancer, by reducing sugar in the diet, or by blocking cells' ability to use sugar. The idea of making the "soil" inhospitable to cancer is a variation on the theme of killing the unwanted tissue.

As long as the lump is defined as an alien material, killing it by any means seems reasonable, but if it is seen as the body's attempt to repair itself, then killing it is no more reasonable than it would be to cut the spots out of someone with smallpox.

When a cell is dying, it emits growth stimulating signals (Huang, et al., 2011). That's a normal part of tissue renewal. Some of its substance guides the differentiation of new cells, as demonstrated long ago by Polezhaev (discussed in my previous article, "Stem cells, cell culture, and culture: Issues in regeneration"). Anything that injures a tissue enough to require cells to be replaced causes the activation of a regulatory protein, hypoxia-inducible factor, HIF, which inhibits mitochondrial respiration, causing a shift toward glycolytic metabolism, increasing substances needed for growth. HIF is essential to the healing of any wound. Even glucose deprivation can cause the induction of HIF. Prostaglandins, made from polyunsaturated fatty acids released by stimulation, can cause HIF to increase, but HIF also causes prostaglandins to increase. Lactic acid increases the expression of HIF, while HIF causes cells to shift metabolically to depend on converting glucose to lactic acid, that is, to adopt the "cancer metabolism." HIF is recognized as a fundamental problem in "cancer therapy," since HIF allows the cancer to resist the treatment, but the treatment increases HIF.

Radiation, chemotherapy, and surgery all activate these processes of cell replacement, and

unless something has changed to improve the organism's recuperative ability, it isn't clear why the cells which replace the missing part should be more able to satisfactorily complete the recovery process than the original cells were. Even the amount of radiation in a single dental x-ray is enough to activate the excitatory-inflammatory processes, and a "therapeutic" x-ray to any part of the body excites similar, but much greater, processes throughout the body. But the ideology of "the cancer cell," and the Gompertz Growth Law, guide the practice of cancer treatment.

Many years ago, Harry Rubin was impressed by hearing from a pathologist that he had been able to find diagnosable cancer somewhere in the body of every person over the age of 50 that he had autopsied. If everyone has cancer by the age of 50, that means that cancer is harmless for most people, and that small cancers might frequently appear, and be spontaneously removed as part of the body's regular house-cleaning. One of the reasons that spontaneous regression of tumors seems so rare is undoubtedly that most tumors are quickly cut out by surgeons.

Preventing injury should be a basic consideration, but the medical slogan, "first do no harm," just doesn't apply to the cancer treatment industry, and this results from the doctrine of "the cancer cell," which is something to be destroyed or kept from multiplying. In the process of diagnosing a cancer, and during the course of treating it, the patient is usually subjected to multiple x-ray examinations, sometimes given radioactive drugs that supposedly concentrate in hidden tumors to emit positrons, and often has toxic contrast agents injected even for MRI examinations. These procedures, even before the destructive "therapies" begin, are adding to the body's inflammatory burden, interfering with the body's ability to complete a healing process. Decisions about pain control usually disregard the effects of the drugs on tumor growth and general vitality--for example, the opiates stimulate histamine release, which increases inflammation and tumor growth.

In 1927, Bernstein and Elias found that rats eating a fat free diet had almost no spontaneous cancer, and many studies since then in animals and people have shown a close association between polyunsaturated fatty acids and cancer. The polyunsaturated fatty acids in themselves, and their breakdown products, are excitatory and destabilizing to normal cells, but by modifying the sensitivity and energy production of cells, they limit cells' ability to respond to stimulation and destabilizing influences. Although they aren't essential for wound healing (Porras-Reyes, et al., 1992), they and their metabolites, the prostaglandins, are very conspicuous in wounds and tumors, and their proportion generally increases with aging. The prostaglandins are involved in several vicious cycles, including that with HIF mentioned above. This makes the PUFA and prostaglandins important to consider in relation to optimizing wound healing, and decreasing cancerization. Aspirin's protective and therapeutic effects in cancer are starting to be recognized, but there are several other things that can synergize with aspirin to reduce the circulation of free fatty acids and their conversion to prostaglandins. Niacinamide, progesterone, sugar, carbon dioxide, and red light protect against both free fatty acids and prostaglandins.

Since excitation leads to intracellular alkalinity and swelling, reducing the excitation seems reasonable, and many things which protect cells against excitation also have demonstrated anticancer effects. Local anesthetics, antihistamines, and anti-inflammatory substances and some anesthetics such as xenon (Weigt, et al., 2009) are safe. Inhibitory substances related to GABA are being investigated for their ability to stop tumor growth. Simply stopping excessive excitation tends to restore the dominance of oxidative respiration over glycolysis.

To restore the supply of oxygen, sugar, and nutrients, swelling must be stopped. Hyperosmotic fluids act directly on swollen cells, removing water. Stopping excitation allows a return to efficient metabolism and reduces the injury potential, allowing the pH to decrease; with lower pH, the cell releases some of its water.

Increasing carbon dioxide lowers the intracellular pH, as well as inhibiting lactic acid formation, and restoring the oxidation of glucose increases CO2. Inhibiting carbonic anhydrase, to allow more CO2 to stay in the cell, contributes to

intracellular acidification, and by systemically increasing carbon dioxide this inhibition has a broad range of protective anti-excitatory effects. The drug industry is now looking for chemicals that will specifically inhibit the carbonic anhydrase enzymes that are active in tumors. Existing carbonic anhydrase inhibitors, such as acetazolamide, will inhibit those enzymes, without harming other tissues. Aspirin has some effect as an inhibitor of carbonic anhydrase (Bayram, et al., 2008). Since histamine, serotonin (Vullo, et al., 2007), and estrogen (Barnett, et al., 2008; Garg, 1975) are carbonic anhydrase activators, their antagonists would help to acidify the hypoxic cells. Testosterone (Suzuki, et al., 1996) and progesterone are estrogen antagonists that inhibit carbonic anhydrase.

With aging, cells have less ability to produce energy, and are often more easily stimulated. The accumulation of polyunsaturated fats is one of the factors that reduce the ability of mitochondria to produce energy (Zhang, et al., 2006, 2009; Yazbeck, et al., 1989). Increased estrogen exposure, decreased thyroid hormone, an increased ratio of iron to copper, and lack of light, are other factors that impair the cytochrome oxidase enzyme.

The increased intracellular alkalinity and intracellular calcium that result from the combination of those factors increase the tendency of cells to be overstimulated, leading to aerobic glycolysis, the cancer metabolism. Improving any part of the system tends to increase carbon dioxide and decrease lactate, permitting differentiated functioning.

There are many people currently recommending fish oil (or other highly unsaturated oils) for preventing or treating cancer, and it has become almost as common to recommend a sugar free diet, "because sugar feeds cancer." This is often, incorrectly, said to be the meaning of Warburg's demonstration that cancer cells have a respiratory defect that causes them to produce lactic acid from glucose even in the presence of oxygen. Cancer cells use glucose and the amino acid glutamine primarily for synthetic purposes, and use fats as their energy source; the growth stimulating effect of the "essential fatty acids" (Sueyoshi and Nagao, 1962a; Holley, et al., 1974) shows that depriving a tumor of those fats retards its growth. The great energetic inefficiency of the cancer metabolism, which causes it to produce a large amount of heat and to cause systemic stress, failure of immunity, and weight loss, is because it synthesizes fat from glucose and amino acids, and then oxidizes the fat as if it were diabetic.

Estrogen, which is responsible for the fact that women burn fatty acids more easily than men, is centrally involved in this metabolic inefficiency. When a tissue is exposed to estrogen, within minutes it takes up water, and begins to synthesize fat, with a tendency to produce lactic acid at the same time. The alkalizing effect of lactic acid production is apparently what accounts for the uptake of water. Since it takes longer, at least 30 minutes, to produce a significant amount of new enzymes, these early changes are explained by the activation of existing enzymes by estrogen.

The transhydrogenases, or the transhydrogenase function of the steroid dehydrogenases, which shift metabolic energy between glycolytic and oxidative systems, have been shown to explain these effects of estrogen, but the transhydrogenases can be activated by many stressors. The biological function of the transhydrogenases seems to be to allow cells to continue growth and repair processes in a hypoxic environment. Estrogen can start the process by creating new pathways for electrons, and will promote processes that are started by something else, and progesterone is estrogen's natural antagonist, terminating the process.

Recently, a group at Johns Hopkins University (Le, et al., 2012) has been working out the implications of this ability to change the metabolism under hypoxia: Using an isotope-labeled amino acid, ". . . glutamine import and metabolism through the TCA cycle persisted under hypoxia, and glutamine contributed significantly to citrate carbons. **Under glucose deprivation, glutamine-derived fumarate, malate, and citrate were significantly increased.**" The implication of this is that if the tumor isn't supplied with sugar, it will increase the rate at which it consumes the host's proteins. Forty years ago the work of Shapot and Blinov was showing the same effect, except that

they demonstrated the involvement of the whole organism, especially the liver, in interaction with the tumor (Blinov and Shapot, 1975).

The alkaline cancer cell surrounds itself by the acid that it emits, and this extracellular acidity increases the ability of fatty acids to enter the cell (Spector, 1969); cancer cells, although they are synthesizing fat, also avidly take it up from their environment (Sueyoshi and Nagao, 1962b). This fat avidity is so extreme that cancer cells *in vitro* will eat enough polyunsaturated fat to kill themselves. This has been offered as proof that fish oil kills cancer. Saturated fats, however, have a calming effect on cancer cells, inhibiting their aerobic glycolysis (Marchut, et al., 1986) while permitting them to resume the respiratory production of energy.

The foods that nourish the patient well enough to support healing while permitting energy reserves to be built up are also the foods that don't interfere with the hormones, that don't cause spurious excitation of the tissues. The polyunsaturated fats directly stimulate the stress hormones, activate the excitatory amino acid signals, and directly excite cells, while the saturated fats have opposite effects, and are anti-inflammatory, and also don't interfere with mitochondrial function. When we eat more carbohydrate than can be oxidized, some of it will be turned into saturated fats and omega-9 fats, and these will support mitochondrial energy production. Carbohydrates in the diet also help to decrease the mobilization of fatty acids from storage; niacinamide and aspirin support that effect. Sugars are probably more favorable than starches for the immune system (Harris, et al., 1999), and failure of the immune system is a common feature of cancer. Polyunsaturated fats are generally known to suppress the immune system. Foods that provide generous amounts of sodium, calcium, magnesium, and potassium help to minimize stress. Trace minerals and vitamins are important, but can be harmful if used excessively--iron excess is important to avoid.

Emodin, an anti-inflammatory substance found in cascara sagrada bark and other plants, is similar to other molecules that have been used for treating cancer, and one of its effects is to lower HIF: "Consistently, emodin attenuated the expression of cyclooxygenase 2 (COX-2), VEGF, hypoxia inducible factor 1 alpha (HIF-1alpha), MMP-1 and MMP-13 at mRNA level in IL-1beta and LPS-treated synoviocytes under hypoxia" (Ha, et al., 2011). MMP-1 and MMP-13 are collagenase enzymes involved in metastasis.

When cells are fully nourished, supplied with protective hormones, and properly illuminated, their ability to communicate should be able to govern their movements, preventing--and possibly reversing--metastatic migration.

Implications of inflammation

It has become widely accepted that inflammation has a central role in several major diseases--atherosclerosis, cancer, Alzheimer's disease, diabetes and obesity, Parkinson's and Huntington's disease, asthma, epilepsy, for example--so understanding the nature of inflammation has gained special importance. For thousands of years, inflammation has been defined by the presence of swelling, redness, increased heat, and pain.

Is the inflammation the main cause of the disease, or is it instead, a response to the disease process? Not long ago, the medical profession began to see inflammation as an important part of the healing process, reflecting the actions of both an innate immunity and a learned immunity, and before that, it was seen, like fever, as the problem to be relieved, with "allopathic" treatments.

Soon after good microscopes were developed, Rudolf Virchow described the collection of white blood cells in infected areas and tumors, and suggested that their accumulation was a consequence of the damage to blood vessels and congestion, caused by tissue damage. They were incidental to the inflammation. A generation later, Elie Mechnikoff, who had studied the orderly and meaningful movements of cells in the developing embryos of a great variety of organisms, saw that the collection of white cells around a foreign material was intentional; in the case of the embryos of starfish, the white cells were part of the organism's digestive system. When he introduced rose thorns into the tissues of water fleas, the wandering cells engulfed and dissolved them. He reasoned that the pus that surrounds a thorn in a person's finger represents the same process--a protective eating and destruction of the harmful material.

For the Greeks and Romans, the pus of an abscess was "laudable," but by Mechnikov's time, pus had become identified with the presence of infectious microorganisms. Disinfectants were used to prevent the infections that could produce pus. However, by the end of the 19th century, sterile extracts of microorganisms were found to be able to produce the inflammatory signs of infection. Virchow's observation of white blood cells in cancers could be considered as an early recognition of sterile inflammation, but the term came into use later, and has appeared intermittently in the literature for many years. The concept has become more important as researchers have explored the interactions between the supposedly primitive, non-specific "innate immunity," and the supposedly more highly evolved specific adaptive immunity.

Trauma, prolonged interruption of blood supply, chemical injury, radiation injury, and signals from nerves are among the things that can cause sterile inflammation.

Although the concept of sterile inflammation has been in the medical literature for a long time, the influence of the drug industry has helped to keep it from entering significantly into medical education. In 1976, I was talking to a recent graduate of Stanford's medical school, and when I mentioned sterile inflammation, she interrupted, saying "there's no such thing, inflammation means that there's an infection." When the involvement of inflammation in neurological disease or atherosclerosis is mentioned, most physicians probably infer that this is evidence of a hidden infection or a mysterious new organism. It could be, but to assume that is to neglect the many other possible causes.

Mechnikov's idea of intentionality, goal directed behavior, in the wandering cells was antagonistic to the most powerful trend in science,

the doctrine of randomness in a mechanistic, deterministic view of matter. Following Descartes, the mechanistic materialists saw living organisms as machines, in which each part interacts mechanically with adjoining parts, and consciousness was something essentially distinct from the living substance of the organism. But as early as the 18th century, some researchers were thinking of the brain as an integrating center, not only for perception and movement, emotion and thought, but even for sickness and health.

The mechanistic materialists labeled such holistic thinking as anthropomorphizing or vitalism. Explanations were considered to lack "objectivity" if they related to a purpose; students were taught to avoid "teleological" explanations, if they wanted to be real scientists. However, from the time of Pasteur and the adoption of mass vaccination, the body's reactions to alien material were concretized in the concept of an "immune system," which existed for the purpose of defending against infections. It's important to remember what scientific knowledge about the nature of life was at that time—almost nothing that people believed at that time about how our bodies come into being, how they produce chemical changes, or how they move and sense, is now recognized as true. But the basic idea of an "immune system" has hardly changed in 100 years.

Although Mechnikov shared the 1908 Nobel Prize with Paul Ehrlich, Ehrlich's Nobel lecture expressed an extremely reductionist view of the organism, almost comical when juxtaposed to Mechnikov's lecture. According to Ehrlich, it was necessary for science to differentiate "the concept of the cell into that of a great number of separate, individual functions." In that lecture he talked about lock-and-key interactions, and receptors on cells. This was the course taken by science in the following century.

Mechnikov's goal directed phagocytes were accepted as part of the immune system that increasingly focused on Ehrlich's highly specific antigens and antibodies. Although the immune system was understood to have the purpose of defending the organism by destroying germs, it was put into an "objective" reductionist mechanistic scheme by giving it its own evolutionary explanation, through the natural selection of random changes in genes which, through time, became a very complicated machine that happened to kill germs, by strictly local molecular interactions. The germ killing, antibody forming immune system was thought to have evolved bit by bit, along with the evolution of the complex nervous, reproductive, and digestive structures and functions that distinguish mammals and people from sponges and roundworms, each feature the result of random changes that were preserved by natural selection.

By the 1960s, because of the ability through "vaccination" to create antibodies that would bind even to newly synthesized substances, the earlier idea of a simply genetically programmed immune system had to be abandoned, because the number of possible antibodies would have required a tremendous amount of DNA, that wouldn't fit inside a cell. New genetic explanations were invented to explain the ability of the immune system to adapt flexibly to unexpected new diseases. This was achieved by the idea of the immune system as a microcosm of evolutionary history, in which hypermutable genes could in a very short time evolve the new sequences needed to produce novel antibodies to destroy novel pathogens. It was still random, but very fast, and the cells that were selected, and stimulated to multiply, formed a clone, the way a mutant cancer cell formed a clone, supposedly giving each tumor its unique genetic individuality.

In an international immunology symposium at the University of Oregon in 1969, a few famous immunologists presented their recently developed theory about immunity, based on the neodarwinian theory of evolution as the result of random changes that are preserved by natural selection. The day after a description, to a large audience, of an experiment demonstrating clonal selection, in which specific immune cell clones were killed in a culture dish, and shown to stay dead, while other clones survived, an assistant professor of developmental biology described, to a small group of students, an experiment in which he had replicated that demonstration of clonal selection, and then repeated the same conditions, but with different concentrations of cells in the dish. With a sparse

cell population in the dish, his results were the same as those described in the earlier lecture, but when he increased the cell population to a certain point, the missing "clones" reappeared.

In the absence of a whole organism, but with a quorum of their peers, the cells were able to reconstitute a full repertoire of sensitivity. My impression as he described the experiment was that it implied that each cell had to have a knowledge of the type of organism it belonged to, rather than just being committed to expressing certain genes for the rest of its life. A few weeks later I met the professor in the hall and asked if he was publishing the experiment, and he said he hadn't written it up yet. I watched for it in the next few years, but never saw anything by him that related to it. Ten years later, a few other people began questioning the clonal deletion theory of self tolerance, but the many changes that have been made subsequently have been essentially to preserve the mechanistic randomness of the theory, and the doctrine that it is a system specifically evolved for fighting microbes. The goal-directedness introduced by Mechnikov was kept for the system as a whole, but the intentionality was reduced to random changes.

This doctrine of a separately evolved, and evolving, immune system provided no insight into the phenomenon of sterile inflammation, and it's that kind of inflammation, which lacks intelligible goal-directedness, that has become so important for understanding the chronic and degenerative diseases, and aging.

Before someone thinks of a mechanistic-neodarwinist theory of sterile inflammation, I want to propose a very different approach. Life is very adaptable, but it isn't infinitely adaptable. Life, in its highly complex forms, whether mollusk, mammal, fungus, or phanerogam, has many common features, and each type has a range of environments that are more or less suitable. The neodarwinian ideology inclines many biologists to assume that an organism's present form represents its best adaptation to its present environment, or to its recent past environments. This leads to arguments that "we evolved to eat ...," or to live in certain ways. But experiments in which animals become more intelligent and live longer when they are put into an environment which never existed in nature imply that organisms have their own internal principles that allow them to become more than they or their ancestors ever were, if they have the right environment.

The intrauterine environment permits injuries to be repaired, mostly without inflammation or scarring, and when some of those features, such as high carbon dioxide and sugar content are provided postnatally, inflammation and scarring can be prevented or reduced.

When prenatal environments are modified, the development of the animal's brain and metabolism is affected, affecting the course of that animal's life, and influencing subsequent generations. The wrong balance of prenatal nutrients can decrease the metabolic rate and increase obesity, or a better balance can increase brain development and alertness. When a young animal's early life is enriched with stimulation and opportunity for exploration, its brain development is improved (increased cortical thickness and enzyme activity), and those changes are passed on to subsequent generations, with cumulative effects if the improved environment continues to be available.

The prenatal absence of inflammation corresponds to conditions that are providing energy and other conditions necessary for a very high rate of metabolism, with minimal stress. Generalizing from an understanding of gestation, we could say that inflammation, and the failure of tissue maintenance, occurring later in life is the result of a gap between the energy that's available and the demands that are made on the organism or on a particular tissue.

This approach to understanding inflammation suggests why it contributes to degenerative processes, and suggests potential remedies, but it also offers a new perspective on the processes that are called innate and acquired immunity. The boundaries of what used to be called an immune system have been expanding and becoming blurred, as the interactions of nerves, hormones, nutrition, tissue repair, reticulo-endothelial system, phagocytosis, and wandering or stem cells come to be understood in more detail.

Jamie Cunliffe and Polly Matzinger have been developing a new understanding of the immune

system, centered on the idea that tissue damage is the main issue, rather than the distinction between self and nonself antigens. They recognize that the old model, especially the "adaptive immune system," is failing to explain things, and they are giving more weight to things such as inflammation that had been attributed to an "innate immune system," but what they are describing might better be described as an alert, intelligent organism maintaining itself.

This new orientation would make "stem cells" part of the "immune system," since they sense danger or tissue damage, and adapt to repair it. The wandering white blood cells, rather than being the end product of a particular clone, are able to transform themselves when they find themselves in new situations, becoming a different kind of cell. The signals that cause them to go where they are needed are related to inflammation, but this is exactly where immunology and stem cell research need to direct their attention. These signals are strongly influenced by environmental conditions.

One of the important features of the intrauterine environment is that it is steadily very warm, and that means that the fats which are synthesized from sugar will be relatively saturated. If sugar is deficient, which is common as a result of maternal hypoglycemia in the third trimester of pregnancy, free fatty acids from the mother's tissues and her diet will provide energy for the fetus.

The brain requires a high level of sugar for optimal growth, so maternal undernutrition or hypoglycemia will increase the ratio of the baby's body weight to its brain weight, and will change various other features of metabolism and structure. If the mother's fats are highly unsaturated, they can be turned into the pro-inflammatory prostaglandins during stress, and hypoglycemia during the third trimester is highly stressful for the fetus. Besides causing injury to the fetus during this time, producing inflammation and potentially scarring and granuloma or fibroma formation, the prostaglandins activate the stress hormones, such as corticotropin release hormone, which is a trigger for stimulating the birth process, and so tend to cause premature delivery.

These polyunsaturated fats, which are clearly alien to the gestational process, interfering in so many ways with optimal development, are present in the mother's tissues and foods because of the type of environment she occupies. If she ate only foods from a warm climate, where plants and animals produce mostly saturated fats, the fetus wouldn't be subjected to the anti-regenerative, pro-inflammatory, anti-developmental effects of the fatty acids and prostaglandins. The polyunsaturated fatty acids, prostaglandins, and inflammation, clearly encroach on the process of gestation, altering the subsequent life of the exposed individuals, causing them to adapt to the world by metabolizing less energy; they continue to constrain development throughout the lives of those who continue to be exposed to them.

The figures for premature births and low birth weight in recent decades suggest the importance of the issue. While adults are getting fatter, more underweight babies are being born. In affluent countries, while the adults' body size has increased during this time, their head circumferences haven't. These changes are similar to those seen in animals fed increased amounts of polyunsaturated fats. Besides being the precursors for the prostaglandins, the polyunsaturated fatty acids amplify inflammation and stress in a variety of other ways.

The prostaglandins are, in adults as they are in the fetus, central to the scarring, fibrosis, and failure of regeneration that are considered to be normal for mammals when they are injured or are aging. The failure of regeneration in a phylum of animals is closely related to their susceptibility to forming tumors. Cancer can be considered as a form of dystrophy, a consequence of tissue atrophy, a failure to keep regenerating. An example of this antagonism would be the experiment in which parts were cut off salamanders, allowing them to grow a new tail or leg, but when a tumor was grafted on where a tail was amputated, the tumor was converted into a tail, by the animal's "regenerative environment."

Before the recognition that adult tissues all contain stem cells, most biologists thought of the organism as being made up of "adult cells," that would last for a large part of a normal life span. Tissues were examined microscopically after they had been killed and hardened chemically, and it didn't occur to most researchers to think of the

image under the microscope as a single frame from a moving picture. G. Zaijecek has done experiments that reveal "cell streaming" in tissues normally thought of as static, such as the liver, pancreas, or the cornea of the eye. It has been recognized for a long time that when the cells of the adrenal cortex are regenerating they "stream" away from the outer capsule, changing their form and function as they go. Zajicek has showed evidence that a similar transformation of function occurs in the pancreas, with acinar cells turning into islet cells as they migrate (Zajicek, et al., 1990).

The innervation of some regenerating epithelial tissues, such as the bladder, skin, and cornea, has been studied in considerable detail, and it's fairly well known that the sensory nerves have complex "trophic" or sustaining effects in these tissue. For example, if sensory nerves are destroyed in an area of the skin, that area becomes thin and shiny. Since some of Pavlov's earliest studies, nerves have been known to have a trophic function on the tissues they innervate. In some tissues–bladder, stomach, heart, liver–complex chemical signals are known to be released by the sensory nerves, but the presence of nerves in other tissues, such as the cortex of the adrenal gland (Heym, et al., 1995), hasn't been so well studied, though all such tissues are known to have nerves. In animals such as salamanders, nerves are known to be involved in the regeneration of lost parts. Nerves are intrinsic parts of cancers, too.

About 50 years ago, a study of the production of blisters produced by hypnotic suggestion found that the blister fluid contained ATP, which had been released by sensory nerves, at the spot that had been touched by what the subject believed was a lighted cigarette. ATP also appears in the fluid of a blister caused by heat, but this example showed how important the sensory nerves are, for things beyond sending messages to the brain. Both ATP, and one of its breakdown products, adenosine, activate some enzymes involved in inflammation. ATP activates the MMP proteinase enzyme that dissolves extracellular matrix, which is a basic step in tissue remodeling, and it also activates a phospholipase which releases arachidonic acid, and the cyclooxygenase enzyme, COX-2, which converts arachidonic acid to prostaglandins.

Besides activating the enzymes to break down the extracellar structure, ATP stimulates cell division and angiogenesis, all of which are normal parts of tissue maintenance. In the bladder, stretching causes the epithelial cells to release ATP, which stimulates sensory nerves; in this situation, the epithelial cells are acting as sense organs, and the ATP acts as a neurotransmitter. It has a similar effect in the breast, in relation to milk ejection (Bowler, et al., 2001). In other tissues, such as bone, mechanical forces also release extracellular ATP, and in this situation it seems to be an important anabolic stimulus to bone growth and repair (Furuya, et al., 2004).

ATP is increasingly recognized (Burnstock, 2007) as a basic neurotransmitter or cotransmitter, but it is something more important and basic than that: it's a constant signal of any cell's presence to neighboring cells. If the concentration of ATP varies too much, it indicates that something is wrong. If a cell is injured or fails to produce enough energy, it leaks ATP. During oxygen deficiency, the leaking ATP causes vasodilation, increasing circulation, and in the respiratory center, it stimulates breathing (Buttigieg and Nurse, 2004; Conde, et al., 2012).

In the prenatal environment, lacking polyunsaturated fatty acids from the environment, ATP is involved in the orderly development of the organism, adjusting rates of growth in a coordinated way. This system, that can be seen in embryology and the early stages of gestation, has all the properties of a self-regulating control system, with a built-in intention to develop in a certain direction. The intention that Mechnikov saw in the phagocyte, is in the whole organism. Cells that will later be thought of as part of "the immune system" are present at the very early stages of embryonic development, participating in its coming into existence. There is no genetic "blueprint" that is being read out for either the organism as a whole or for an immune system that has evolved to deal with infectious challenges. The system creates and discovers its potential, in a unique way, responding to what its environment provides it.

Not long ago, following the cult of the "Weismann barrier," it was believed that oocytes were "read out" at an early stage of development, from a genetic blueprint that would never be accessible again. That doctrine lasted for 100 years, until someone tested it (Johnson, et al., 2004, 2005; Bukovsky, et al., 2005; White, et al., 2012). As they showed, the embryo and the adult are intentional unities, able to improvise in surprising ways, but genetics and immunology have created fragmentary, mechanistic descriptions of them.

During development, the coordinated growth and functioning of the system is affected by the chemicals in the environment that the organism encounters. The prostaglandins reflect a particular ecosystem in which plants produce certain unsaturated fatty acids, but biomedical ideologues have idealized them, following the doctrine that this is the environment that we evolved to live in. This is very much like the nutrition professor at Oregon State University who taught students that white bread should be included in the diet because God gave it to us.

Lacking PUFA and prostaglandins, extracellular ATP would activate constructive pathways, tending to create a new equilibrium, without producing all of the harmful effects of the prostaglandins. As unstable polyunsaturated fats accumulate in the tissues with aging, they increasingly promote vicious circles of stress (some of those were described in Fats, Functions & Malfunctions).

Recognizing a mismatch between the organism's potentials and the present environment, and suggesting ways to improve the environment, isn't anything new, and a limited form of it has been institutionalized in various offices of occupational health and safety, traffic safety, and pollution control, but it conflicts with the other well-institutionalized attitude, that people must be changed to conform to the situation as it is. Eugenics, sterilization, vaccination, health education, and publicity campaigns explaining why cancer, heart disease, and obesity are caused by choices the individual makes, are well financed and supported by large organizations.

The idea of autoimmunity epitomizes this general situation, in which reductionist theories are invoked to explain why a person is causing his own sickness. If antibodies evolved to attack microbes, then the immune system has become defective when it produces antibodies against its own tissue. But if the system of wandering cells, complement, antibodies, etc., has to do with development and maintenance of the organism, the presence of antibodies and other "immune" factors would be expected whenever a tissue is damaged.

Simply twisting a piece of cartilage has been shown to make it antigenic, and many other things causing sterile inflammation cause antibodies to appear. Strokes or other brain injuries cause antibodies to be produced. The presence of auto-antibodies has been found to facilitate the recovery from an aseptic inflammatory condition of the brain, accelerating healing and re-vascularization (Hofstetter, et al., 2003). Intravenous immunoglobulin has a long history of use to reduce inflammation (Nimmerjahn and Ravetch, 2008), and it has been tested as a treatment for heart failure, producing anti-inflammatory effects (Aukrust, et al., 2006).

Components of the complement system and C-reactive protein, which are increased by tissue injury, are involved in the anti-inflammatory clearance of dying cells (Gershov, et al., 2001).

The presence of the "essential fatty acids" is an important factor in the allergenicity of transplanted tissues (Schreiner, et al., 1988), which might be expected, from the role of the prostaglandins in creating inflammation whenever a tissue is stressed.

Many types of evidence indicate that environmental PUFA and prostaglandins produced from the "essential" fatty acids are required for inflammation to progress to degeneration. The n-9 polyunsaturated fatty acids (the kind that we can make from saturated fat or sugar) seem to be positively protective against inflammation. For example, rats fed a diet with 2% hydrogenated coconut oil for two weeks had lower levels of IL-6 and C-reactive protein than when a small amount of arachidonic acid and docosahexaenoic acid (DHA) were added. Mead acid (20:3n9) was lower in the group with the PUFA supplement,

and the inflammatory reaction to endotoxin was greater in the supplemented group (Ling, et al., 2012).

Many of the things that can be achieved by vaccination and treatment with safe anti-inflammatories such as aspirin could be done better by long-term changes of diet, and by taking into account the interactions of the hormones, especially progesterone, estrogen, and thyroid, with nutrients and stressors. But much more than that is needed: The nature of the relationships between environmental factors and the body's reactions has to be clarified, so that the processes of healing and regeneration can more closely resemble the prenatal condition, possibly even continuing in adulthood the "pedomorphic" process, realizing human potentials that haven't previously been seen.

When energy fails: Edema, hypertension, heart failure sarcopenia, cramps, etc.

More than 100 years ago the idea of a morphogenetic field was proposed by A.G. Gurwitsch, as a way to explain the orderly movements of cells in embryos and growing tissues, and to understand the principles that cause cells to change appropriately when their location in the organism changes. For 30 years, the concept guided research in embryology, but also led to important discoveries in the biology of cancer, aging, wound repair, and other important areas. But by the late 1940s, a more abstract approach to biology, based on the gene doctrine of Mendel and Weismann, took charge of academic and governmental biological research. This ideology at first said that organisms are determined by unchanging units of inheritance, "genes," and later when genes were found to be susceptible to mutation, the changes were said to be always random. The Central Dogma of the ideology was that any meaningful, adaptive changes that occur in an organism can't influence the genes. For many years, adaptive changes were said to be nothing but changes in the size or function of existing cells, because the cells of the major organs of the body were supposed to be created before birth, or in infancy.

Besides the purely ideological commitment to the theory of genes, there were other influences that contributed to the culture of Molecular Biology. People learned histology from slides or pictures made by killing, hardening, dehydrating, and slicing parts of organisms. Biochemists studied the chemistry of life mainly by grinding cells or tissues, and extracting water soluble materials to study the actions of enzymes on various materials. These unrealistic artifacts filled the textbooks and the minds of generations of biologists and physicians. The culture of molecular biology used these artifacts to create theories of embryology and physiology, and holistic ideas such as the developmental field were disregarded.

The mental image of a living organism that has been created by that culture is simply wrong. The concept of a developmental field is essential for understanding embryology, because things that exist on a scale bigger than molecules and cells govern the functions of the molecules and cells, and the principles of embryology don't arbitrarily stop operating at birth, but can be seen to continue operating during maturity and aging. The interactions of cells with their environment are different at different stages of life, but there are commonalities that are extremely important.

The processes that govern the pregnant woman's blood circulation, in sustaining the development of a fetus, are very similar to the processes that govern anyone's blood circulation, providing for the maintenance and renewal of all the body's organs. The common problems of pregnancy involving the circulatory system can provide insights into the problems of the various organs that have been the focus of the medical specialties, and into some basic medical issues, including aging, obesity, and inflammation.

The development of a fertilized egg into an embryo consumes energy at a very high rate, and the way the embryo develops depends on a continuously adequate supply of oxygen and sugar, and other nutrients. The intense flow of energy through each stage of a developing structure shapes the following stage. The necessary energy and materials are provided abundantly by the mother's blood. When the development has advanced far enough to make life possible outside the uterus, energy will be used more slowly, for growth, maintenance, and renewal of tissues.

Failure to renew cells and tissues leads to the loss of function and substance. Bones and muscles get weaker and smaller with aging. Diminished bone substance, osteopenia, is paralleled, at roughly the same rate, by the progressive loss of muscle mass, sarcopenia (or myopenia). The structure of aging tissue changes, with collagen tending to fill the spaces left by the disappearing cells. It's also common for fat cells to increase, as muscle cells disappear.

When conditions are ideal, as during healthy development in the uterus, tissue damage is corrected by the multiplication of cells to replace any that were lost. But when conditions are less perfect, injuries are imperfectly repaired, usually with highly collagenous scar tissue bridging the area that was destroyed. During this imperfect repair, there is inflammation, which apparently exists to the extent that the substances needed for regeneration are lacking. For example, when oxygen is lacking, lactic acid is likely to be produced, along with increases of pro-inflammatory regulators such as histamine and serotonin, leading to the loss of many important proteins and functions, and the over-production of collagen instead.

Since cellular renewal of tissues, in a healthy individual, is a constant process, we can think of the metabolic rate of a healthy adult as just what is needed to sustain this constant, limited sort of regeneration, but not quite intense enough to produce scarless healing of a wound (without special intervention).

If something reduces the systemic ability to produce energy, there will be a gap between the available energy and the energy needed for the constant turnover of cells in each tissue and organ, and a generalized inflammation will develop. The replacement of cells will be slowed, and the organism will mobilize the processes used for producing scar tissue, producing an excess of collagen, filling the spaces left by the lost cells.

We are susceptible to many things that interfere with energy production—the substitution of iron for copper in the respiratory enzyme, the absorption of endotoxin, the accumulation of PUFA, a deficiency of thyroid hormone, the formation of increased amounts of nitric oxide, serotonin, and histamine, etc. Different environments will condition the way the defensive mechanisms of inflammation are produced.

Toxemia of pregnancy, or preeclampsia, is a state of generalized inflammation, and some of the causes and remedies are known. Despite the predominance of crazy genetic theories of preeclampsia in 20th century medical literature, there was clear evidence (reviewed by Tom Brewer, Douglas Shanklin, and Jay Hodin) that it was caused by malnutrition, and that it could be cured by adequate protein, salt, and calcium.

The old medical practice of restricting salt intake during pregnancy was an important factor in causing it, so it's interesting to look at the effects of salt restriction as a treatment for hypertension.

The pregnant woman's blood volume expands, to permit the supply of energy to match the needs of the embryo. If the blood volume doesn't increase, or if it decreases, as in pregnancy toxemia, her blood pressure will increase. Typically, the decrease of blood volume is accompanied by an increase in the extracellular fluid, edema, resulting from leakage of fluid through the walls of the capillaries, and albumin appears in the urine as it leaks through the capillaries in the kidneys. The amount of blood pumped by the heart, however, is increased in toxemia (Hamilton, 1952), showing that the increased blood pressure is at least partially compensating for the smaller volume of blood.

A similar situation, reduced blood volume and edema, can be seen (Tarazi, 1976) in "essential hypertension," the "unexplained" high blood pressure that occurs more often with increasing age and obesity. At the beginning of "essential hypertension," the amount of blood pumped is usually greater than normal.

In both situations, preeclampsia and essential hypertension, there is an increased amount of aldosterone, an adrenal steroid which allows the kidneys to retain sodium, and to lose potassium and ammonium instead. A restriction of salt in the diet causes more aldosterone to be produced, and increased salt in the diet causes aldosterone to decrease. One effect of aldosterone is to increase the production of a substance called vascular

endothelial growth factor, VEGF, or vascular permeability factor, which causes capillaries to become leaky, and causes new blood vessels to grow.

While increased salt in the diet tends to lower both aldosterone and VEGF, reducing the leakiness of blood vessels, sodium also has a direct effect that tends to prevent the leakage of water and albumin out of the blood vessels, helping to maintain the blood volume which is needed to perfuse the kidneys, preventing them from producing signals to increase blood pressure and aldosterone. There is a large amount of albumin in the blood serum, and sodium ions associate with the negative electrical charges on the albumin molecule. This association causes the complex of albumin and sodium to attract a large amount of water, that is to exert osmotic or oncotic pressure. This oncotic pressure causes any excess extracellular water to be attracted into the blood vessels, preventing edema while maintaining the blood volume. When there is too little sodium, the albumin molecule itself easily leaves the blood stream along with the water.

Instead of considering the significance of sodium's effects on albumin, aldosterone, and VEGF, textbooks have often talked about the factors that "pump" sodium, and factors that specifically regulate the movement of water. Experiments in which an excess of aldosterone is combined with a high salt intake produce increased blood pressure, and--by invoking various genes--salt is said to cause hypertension in certain people. This reasoning is hardly different from the reasoning of the drug companies in the 1950s who said that since women with toxemia have hypertension and edema, they should be treated with a diuretic and a low salt diet, to eliminate water and to reduce blood pressure.

The physiological loss of sodium occurs when energy metabolism fails, as in diabetes, hypothyroidism, hyperestrogenism, and starvation. What these conditions have in common is an increased level of free fatty acids in the blood. Increased free fatty acids impair the use of glucose. The consumption of carbohydrate, like an increase of thyroid hormone, insulin, or progesterone, increases the retention of sodium; fructose is the most effective carbohydrate (Rebello, et al., 1983).

The loss of sodium is often accompanied by the retention of water, reducing the osmotic pressure of the body fluids. The leakiness of blood vessels allows the extracellular fluid volume to increase, as understood in the standard definition of edema. However, when this fluid is hypo-osmotic, it will enter cells, causing them to swell. Cell swelling excites cells (Ayus, et al., 2008; Baxter, et al., 1991), and can kill them if they are unable to produce enough energy to restore their original volume, by measures including the excretion of amino acids and potassium. Both low sodium (hyponatremia) and low osmotic pressure stimulate the adrenergic nervous system.

The increase of adrenalin, caused by a deficiency of sodium, is one of the factors that can increase blood pressure; if the tissues's glycogen stores are depleted, the adrenalin will mobilize free fatty acids from the tissues, which tends to inhibit energy production from glucose, and to increase leakiness. After I had read Tom Brewer's work on preventing or curing preeclampsia with added salt, I realized that the premenstrual syndrome involved some of the features of preeclampsia (edema, insomnia, cramps, hypertension, salt craving), so I suggested to a friend that she might try salting her food to taste, instead of trying to restrict salt to "prevent edema." She immediately noticed that it prevented her monthly edema problem. For several years, all the women who tried it had similarly good results, and often mentioned that their sleep improved. I mentioned this to several people with sleep problems, and regardless of age, their sleep improved when they ate as much salt as they wanted. Around that time, several studies had shown that salt restriction increases adrenalin, and one study showed that most old people on a low sodium diet suffered from insomnia, and had unusually high adrenalin. When they ate a normal amount of salt, their adrenalin was normalized, and they slept better.

It's very common for physicians who are aware of progesterone's "anti-aldosterone" activity to think that both estrogen and progesterone are responsible for the increased risk of sodium loss in women, especially during pregnancy, but Hans

Selye demonstrated that progesterone will normalize sodium retention even when there is no aldosterone at all, following removal of the adrenal glands. It is estrogen which is responsible for the dangerous loss of sodium.

The ratio of estrogen to progesterone—regardless of age or gender—is an important factor in regulating minerals and water, cell energy metabolism, and blood pressure. The ratios of many other regulatory substances (including serotonin/dopamine, glucagon/insulin, and aldosterone/cortisol+progesterone) vary according to the quality of the individual's level of adaptation to the environment. Improving the environment can shift the ratio in the direction of restoration, rather than mere survival.

Gershom Zajicek and his colleagues have demonstrated an organized renewal of tissues, in which new cells are born with the division of stem cells, and "stream" away from their origin as they mature, and finally are shed or dissolved. A few studies have demonstrated a similar kind of migration of new cells in the brain (Eriksson, et al., 1998; Gould, et al., 1999), a process which differs by the absence of systematic dissolution of mature brain cells. While Zajicek has demonstrated the conversion of one kind of cell, such as a pancreatic ductal epithelial or acinar cell into insulin-secreting beta cells, other researchers have shown that after injury to the pancreas beta cells can be formed from glucagon-secreting alpha cells, as well as from other beta cells.

Stress, increasing the need for energy, increases the formation of cortisol and free fatty acids when glucose isn't available, and those—while they provide alternative sources of energy—interfere with the ability to produce energy from glucose. Free fatty acids and cortisol can cause the insulin-secreting beta cells to die. Glucose, and insulin which allows glucose to be used for energy production, while it lowers the formation of free fatty acids, promote the regeneration of the beta-cells. Although several research groups have demonstrated the important role of glucose in regeneration of the pancreas, and many other groups have demonstrated the destructive effect of free fatty acids on the beta cells, the mainstream medical culture still claims that "sugar causes diabetes."

In the adrenal glands, renewing cells stream from the capsule on the surface of the gland toward the center of the gland. The first cells to be produced in a regenerating gland are those that produce aldosterone, the next in the stream are the cortisol producing cells, and the last to be formed are the cells that produce the sex hormones, the androgens including DHEA, and progesterone. In aging, after the age of thirty, the renewal slows, but the dissolution of the sex hormone zone continues, so the proportion shifts, increasing the ratio of the aldosterone and cortisol producing cells to the layer that produces the protective androgens and progesterone (Parker, et al., 1997).

Even before aldosterone was identified, progesterone's role in regulating the salts, water, and energy metabolism was known, and after the functions of aldosterone were identified, progesterone was found to protect against its harmful effects, as it protects against an excess of cortisol, estrogen, or the androgens. New anti-aldosterone drugs are available that are effective for treating hypertension and heart failure, and their similarity to progesterone is recognized.
